Hypermagnesemia is a fairly rare disorder. Under normal circumstances, the kidneys increase magnesium excretion as the magnesium load increases. A healthy adult can excrete more than 6 g of magnesium daily. For this reason, clinically significant hypermagnesemia is encountered almost exclusively in the setting of renal insufficiency (Box 123-13). Serum magnesium levels rise as the creatinine clearance falls below 30 mL/min and typically reach approximately 2.5 mEq/L as renal function nears zero. Although severe renal failure alone can cause symptomatic hypermagnesemia, this is more likely when a patient with preexisting renal failure is challenged with an exogenous magnesium load. Clinically significant
hypermagnesemia can be produced even by usual therapeutic doses of magnesium-containing preparations in patients with renal insufficiency. Elderly patients misusing over-the-counter medications are particularly at risk.

Iatrogenic hypermagnesemia can result from parenteral magnesium administration, excessive magnesium in dialysate solutions, or ingestion of magnesium-containing antacids or laxatives. Severe hypermagnesemia occurs rarely in the patient with normal renal function, but only when such massive magnesium loads are administered that magnesium absorption exceeds the normal renal excretory capacity. IV magnesium infusion for the treatment of preeclampsia and eclampsia is a common cause of hypermagnesemia but leads to problems only when excessive doses are given or when renal function is compromised. Another situation particularly relevant to the emergency physician is multidose administration of magnesium-containing cathartics during overdose management. Although several case reports document severe hypermagnesemia in this setting, clinically significant hypermagnesemia is rare in the absence of preexisting renal insufficiency. A review of 102 patients receiving multiple doses of magnesium citrate during overdose management (mean dose, 9.22 g) reported only modest rises in serum magnesium, with no clinically significant side effects. Decreased gastrointestinal motility may cause an increase in the absorption of magnesium-containing substances and result in toxicity. This may occur after the ingestion of certain drugs (e.g., anticholinergics, narcotics) or in patients with hypomotility disorders (e.g., chronic constipation, colitis, bowel obstruction, gastric dilation). Although symptomatic hypermagnesemia is more likely in patients with preexisting renal insufficiency, it has been reported in patients with normal renal function.

Other, less common causes of hypermagnesemia include rhabdomyolysis, tumor lysis syndrome, adrenal insufficiency, hyperparathyroidism, hypothyroidism, and lithium therapy.

Clinical Features

The clinical manifestations of hypermagnesemia generally correlate well with the serum level. Early signs of hypermagnesemia, including nausea, vomiting, weakness, and cutaneous flushing, usually appear at serum levels of approximately 3 mg/dL. As levels rise above 4 mg/dL, hyporeflexia is seen, and deep tendon reflexes are eventually lost. Hypotension and ECG changes (e.g., QRS widening, QT and PR prolongation, conduction abnormalities) are seen at serum levels of 5 to 6 mg/dL. Levels greater than 9 mg/dL are associated with respiratory depression, coma, and complete heart block. Although hypermagnesemia may decrease the anion gap, numerous cases of hypermagnesemia with a normal anion gap have been reported.

Management

The first step in the management of hypermagnesemia is to discontinue all exogenous magnesium. Further treatment depends on the clinical presentation, the degree of hypermagnesemia, and the patient’s underlying renal function. Patients with mild symptoms and normal renal function may require only observation. If more prominent symptoms are present, hydration with isotonic fluids and administration of IV furosemide can be used to accelerate magnesium elimination. If these measures are used, the serum potassium level should be closely monitored.

Patients with severe hypermagnesemia should receive IV calcium. Calcium directly antagonizes the membrane effects of hypermagnesemia and reverses respiratory depression, hypotension, and cardiac dysrhythmias. For life-threatening manifestations of hypermagnesemia, 100 to 200 mg of calcium, as either 10% calcium gluconate (93 mg calcium per ampule) or 10% calcium chloride (360 mg calcium per ampule), is a reasonable dose. Repeat boluses or a continuous infusion (2–4 mg/kg/hr) may be required to sustain the effect while measures to increase magnesium elimination are instituted. Dialysis should be considered in patients with coma, respiratory failure, or hemodynamic instability and in those with severe hypermagnesemia associated with renal failure.

### PHOSPHORUS

#### Normal Physiology

Phosphorus is located primarily in the cell complexed with oxygen and hydrogen as phosphate. In this form, phosphate is an important component of nucleic acids (RNA and DNA) and of the phospholipid cell membrane. Phosphate is an essential component of ATP, the energy currency of all living cells, and of erythrocyte 2,3-diphosphoglycerate (2,3-DPG), which promotes the release of circulating oxygen at the tissue level. Phosphate also binds with calcium to form hydroxyapatite, the major salt of bone matrix.

In the serum, phosphate is an important acid-base buffer. In the presence of acidsosis, divalent phosphate (HPO\textsubscript{4}\textsuperscript{2−}) binds excess hydrogen ions, shifting to the monovalent form (H\textsubscript{2}PO\textsubscript{4}−). The reverse occurs when the extracellular fluid becomes alkalotic.

The normal adult human body contains approximately 700 g of phosphate, 80% of which is contained in the mineral component of bone. Phosphate balance is maintained by three different organs: intestine, kidney, and bone. PTH and vitamin D are the major hormonal regulators of plasma phosphate concentration, although these hormones are released in response to changes in Ca\textsuperscript{2+} rather than phosphate. Normal serum phosphate levels range from 3 to 4.5 mg/dL.
Dietary sources of phosphate include fruits, vegetables, meats, and dairy products. Absorption of ingested phosphate occurs through active and passive transport in the small intestine. Vitamin D enhances the absorption of both phosphate and calcium.

In the kidneys, 90% of the filtered load of phosphate is reabsorbed in the proximal tubule. Renal reabsorption increases in deficiency states. When serum phosphate levels increase, renal reabsorption decreases. PTH acts at the proximal and distal tubules to inhibit phosphate resorption. In the absence of normal renal function, PTH cannot increase phosphate excretion and may actually increase serum phosphate levels because of its effect on intestine and bone. Thyroid hormone and growth hormone both increase renal phosphate resorption.

The release and uptake of phosphate by bone are primarily determined by the mechanisms governing calcium metabolism. When the serum calcium level falls, both calcium and phosphate are released into the extracellular space by the action of PTH. When serum calcium levels rise, bone formation increases, and phosphate and calcium shift from the serum into bone.

### Hypophosphatemia

#### Principles of Disease

Hypophosphatemia has traditionally been classified as mild (2.5–2.8 mg/dL), moderate (1.0–2.5 mg/dL), or severe (<1.0 mg/dL). The incidence of hypophosphatemia in hospitalized patients is 2 to 3% and as high as 30% in those admitted to the intensive care unit. Severe hypophosphatemia is seen in up to 0.5% of hospitalized patients. Important risk factors include DKA, malnutrition, diuretic or antacid therapy, sepsis, and alcoholism. The many causes include (1) disorders that result in increased renal excretion, (2) disorders that are associated with decreased gastrointestinal absorption, and (3) disorders in which phosphate shifts from the serum into cells (Box 123-14).

Renal phosphate loss is most often the result of diuretic therapy. The thiazides, loop diuretics, and acetazolamide promote renal phosphate wasting. Hypophosphatemia can also be seen in patients with acute renal failure, renal transplantation, and long-term peritoneal dialysis, although renal insufficiency is typically associated with hyperphosphatemia rather than hypophosphatemia. In hyperparathyroidism, high levels of circulating PTH increase renal phosphate excretion and may cause hypophosphatemia.

DKA is an important cause of hypophosphatemia. Metabolic acidosis and insulin deficiency mobilize intracellular phosphate stores, and in the setting of an ongoing osmotic diuresis, urinary losses increase. Because of a shift of phosphate from cells to the blood, serum levels may be normal in the face of a profound total deficit. Treatment of DKA with insulin causes phosphate to move back into cells and may result in a sharp decline in the serum level. The benefit of routine phosphate replacement in DKA is unproven, although patients with low serum phosphate levels in the face of acidosis should be presumed to have a severe deficiency. Because these patients are often hypokalemic, replacement with potassium phosphate salts is a reasonable approach.

Decreased phosphate intake and impaired intestinal phosphate absorption are other causes of hypophosphatemia. Up to 50% of alcoholics are hypophosphatemic. Increased renal excretion and decreased intake are the proposed mechanisms. Hypophosphatemia may be exacerbated when glucose-containing solutions are administered, because these cause phosphate to shift from the serum into cells.

Because phosphate is ubiquitous in most food sources, starvation and chronic malnutrition are relatively uncommon causes in the developed world, although low-birth-weight infants are particularly vulnerable. Decreased intestinal phosphate absorption occurs in malabsorptive syndromes, chronic diarrhea, and vitamin D deficiency. Phosphate-binding antacids (calcium carbonate, aluminum hydroxide, aluminum carbonate) prevent the absorption of dietary phosphate, and long-term therapy can lead to hypophosphatemia.

Transcellular shifts of phosphate from the extracellular space into cells is the third mechanism of hypophosphatemia. Respiratory alkalosis is a common cause of hypophosphatemia. Reduction of intracellular carbon dioxide tension increases the activity of phosphofructokinase, the rate-limiting enzyme of glycolysis, and phosphorylation of glucose precursors increases cellular uptake of serum phosphate, causing hypophosphatemia. Hyperventilation-induced hypophosphatemia may occur in the setting of sepsis, heatstroke, salicylate poisoning, neuroleptic malignant syndrome, hepatic encephalopathy, alcohol withdrawal, and acute panic disorders.

The administration of glucose-containing solutions to chronically malnourished patients can precipitate the so-called refeeding syndrome, in which insulin release increases cellular phosphate uptake, decreasing the serum concentration. This can be prevented by adding supplemental phosphate to the diet. Beta-receptor agonists used in the management of acute asthma stimulate cellular uptake of phosphate and can precipitate hypophosphatemia. Administration of catecholamines and sodium bicarbonate also shifts phosphate into the cell. Increased metabolic demands in postoperative patients increase cellular phosphate uptake and can cause a deficiency state. Certain rapidly growing malignancies (e.g., leukemia, Burkitt’s lymphoma, histiocytic lymphoma) also take up enough phosphate to cause hypophosphatemia.

Causes of Hyperphosphatemia

- Pseudohyperphosphatemia
- Paraproteinemia
- Hyperlipidemia
- Hemolysis
- Hyperbilirubinemia

Renal
- Acute and chronic renal failure
- Increased renal tubular reabsorption
  - Hypoparathyroidism
  - Thyrotoxicosis
  - Excess vitamin D administration

Cellular injury
- Rhabdomyolysis
- Tumor lysis syndrome
- Hemolysis
- Increased intake
  - Phosphate enemas or laxatives
  - Intravenous or oral phosphate administration

This may result in hemolysis and increased destruction in the spleen. Hypophosphatemia is also associated with leukocyte dysfunction with impaired chemotaxis, phagocytosis, and opsonization, increasing the susceptibility to infection.

Neurologic manifestations of severe hypophosphatemia include weakness, confusion, seizures, and coma. Peripheral neuropathy and an ascending motor paralysis resembling Guillain-Barré syndrome have been reported.

Management

The treatment of hypophosphatemia depends both on the serum level and on the severity of symptoms. Mild or moderate hypophosphatemia can usually be treated with oral supplements such as potassium phosphate. Severe hyperphosphatemia should be treated with IV phosphate. Two preparations are available: potassium phosphate and sodium phosphate. Because hypophosphatemia and hypokalemia can coexist in some disorders (e.g., DKA, alcoholism), replacement with the potassium salt is most appropriate.

Complications of IV phosphate administration include acute hypocalcemia and hyperphosphatemia. Patients should be monitored for signs of hypocalcemia, such as tetany. Phosphate should be administered with particular caution in patients with renal dysfunction.

Hyperphosphatemia

Principles of Disease

Hyperphosphatemia (>5.0 mg/dL) is rare in patients with normal renal function because the kidneys readily excrete an excess phosphate load. True hyperphosphatemia can result from decreased phosphate clearance, an increased endogenous phosphate load, or an increased exogenous load (Box 123-16).

Pseudohyperphosphatemia represents a spurious elevation of inorganic phosphate measurements caused by interference with analytic methods. Causes include paraproteinemia (e.g., multiple myeloma), hyperlipidemia, hemolysis, and hyperbilirubinemia.

Renal failure is the most common cause of hyperphosphatemia. The serum phosphate level typically remains normal until the creatinine clearance falls below 30 mL/min.

Clinical Features of Hypophosphatemia

Cardiovascular
- Decreased contractility
- Hypotension
- Dysrhythmias
- Cardiomyopathy

Pulmonary
- Respiratory failure
- Ventilator dependence

Skeletal Muscle
- Weakness
- Myalgias
- Rhabdomyolysis

Hematologic
- Decreased tissue oxygen delivery
- Hemolysis
- Leukocyte dysfunction
- Platelet dysfunction

Neurologic
- Paresthesias
- Seizures
- Coma

Clinical Features

The signs and symptoms of hypophosphatemia result from impaired production of ATP and inadequate energy metabolism. Virtually every organ system can be affected (Box 123-15). Mild or moderate hypophosphatemia is usually asymptomatic, and major clinical sequelae are usually seen only in severe hypophosphatemia.

With severe phosphate depletion, myocardial depression is seen, and hypotension, impaired pressor responsiveness, and left ventricular dysfunction have been reported. Hypophosphatemia also reduces the threshold for ventricular dysrhythmias.

Respiratory insufficiency is common among severely hypophosphatemic patients. Decreased energy substrate leads to respiratory muscle weakness, depressed diaphragmatic contractility, hypoxia, and respiratory acidosis. Rapid correction of chronic respiratory acidosis with assisted ventilation may decrease the serum phosphate level further by shifting the anion into the cell. Inability to wean a ventilated patient may be an important consequence of hypophosphatemia.

The effects of hypophosphatemia on skeletal muscle are also related to depletion of intracellular ATP. Symptoms include muscle weakness, myalgias, and fatigue. Hypophosphatemia can cause rhabdomyolysis. This may be asymptomatic, manifested only by increased serum muscle enzyme levels, or may cause severe muscle pain and weakness and acute renal failure. Rhabdomyolysis may be precipitated by acute alcohol withdrawal, by the treatment of DKA, and in hypophosphatemic patients by hyperalimentation. Significant rhabdomyolysis results in the release of phosphate from muscle cells, and serum phosphate levels can be normal or even high despite intracellular hypophosphatemia.

Hypophosphatemia results in impaired production of 2,3-DPG in the erythrocyte, causing a leftward shift of the oxyhemoglobin dissociation curve and decreased tissue oxygen delivery. In the absence of adequate ATP stores, the erythrocyte is unable to maintain membrane integrity and the ability to deform and alter its shape as it passes through capillaries.
phosphatemia is usually mild unless an exogenous phosphate load is given. Hyperphosphatemia may also occur in patients with normal renal function when renal phosphate resorption is increased, as occurs with PTH deficiency, and in the setting of thyrotoxicosis or excessive vitamin D administration.

Hyperphosphatemia can also occur with large endogenous phosphate loads, as with extensive cell damage, which causes phosphate to be released into the extracellular space. This may occur in the setting of rhabdomyolysis, tumor lysis syndrome, or hemolysis. Patients with these disorders often develop renal failure, impairing phosphate excretion and further increasing serum levels.

Hyponatremia affects the central nervous system, causing lethargy, apathy, confusion, disorientation, agitation, depression, and psychosis.

Management

The emergency treatment of hyperphosphatemia involves supportive care and treatment of symptomatic hypocalcemia. In patients with normal renal function, infusion of isotonic saline increases phosphate clearance. The administration of dextrose and insulin drives phosphate into cells, temporarily lowering the serum level.

Aluminum-containing antacids are the mainstay of the prevention of hyperphosphatemia in patients with chronic renal failure. Although these are usually not administered in the emergency department, their use is reasonable in the management of hyperphosphatemia after a large overdose of exogenous phosphate. When hyperphosphatemia poses a threat to life, hemodialysis or peritoneal dialysis should be considered, especially in patients with renal failure.

Key Concepts

- Hyponatremia affects the central nervous system, causing lethargy, apathy, confusion, disorientation, agitation, depression, and psychosis.
- Treatment of hyponatremia is based on severity of symptoms, estimated duration of illness, and patient’s volume status. Patients with acute hyponatremia are usually symptomatic (e.g., severe weakness, diminished consciousness, seizures) when the serum Na⁺ level falls below 120 mEq/L, whereas patients with chronic hyponatremia can tolerate much lower levels.
- Acute hyponatremia may be corrected at rates of up to 1 to 2 mEq/L/hr, and chronic hyponatremia should be corrected at a rate not greater than 0.5 mEq/L/hr. In general, the serum Na⁺ level should not be increased by more than 10 mEq/L in a 24-hour period.
- Oral therapy for hypokalemia is preferable to IV therapy because of the risk of inducing hyperkalemia through the IV route. However, patients with prominent symptoms (e.g., dysrhythmias) and those who are unable to tolerate oral supplements should receive IV potassium replacement.
- The ECG can provide valuable clues to the presence of hyperkalemia (e.g., peaked T waves, loss of P waves, QRS widening).

- Treatment of hyperkalemia includes cardiovascular monitoring, administration of calcium for hemodynamic instability, lowering of serum K⁺, and correction of the underlying disorder.
- Treatment of hypercalcemia (IV fluids, furosemide, osteoclastic inhibitors, e.g., bisphosphonates [etidronate, pamidronate], plicamycin, calcitonin, glucocorticoids, and gallium nitrate) should be initiated in patients with significant symptoms (e.g., severe dehydration, alteration of consciousness, dysrhythmias) or when the calcium level is above 14 mg/dL. The goals of therapy are normalization of volume status, enhancement of renal calcium elimination, diminution of osteoclastic activity, and treatment of the underlying disorder.
- In hypomagnesemia, although the serum magnesium level often inaccurately reflects total body stores, magnesium supplementation should be considered when the level is less than 1.2 mg/dL. IV magnesium therapy should be instituted for patients with significant symptoms (e.g., seizures, dysrhythmias).

Diabetes Mellitus and Disorders of Glucose Homeostasis

Rita K. Cydulka and Gerald E. Maloney, Jr.

PERSPECTIVE

Diabetes mellitus is the most common endocrine disease. It comprises a heterogeneous group of hyperglycemic disorders characterized by high serum glucose and disturbances of carbohydrate and lipid metabolism. Acute complications include hypoglycemia, diabetic ketoacidosis (DKA), and hyperglycemic hyperosmolar nonketotic coma (HHNC). Long-term complications include disorders of blood vessels, especially the microvasculature. The cardiovascular system, eyes, kidneys, and nerves are particularly susceptible to complications. Despite the discovery of insulin more than 75 years ago by Banting and Best, the incidence of severe debilitating complications, including arteriosclerosis, renal failure, retinopathy, and neuropathy, remains high. The Diabetes Control and Complications Trial proved that tight blood glucose control reduces the risk of these late sequelae for type 1 diabetics. The United Kingdom Prospective Diabetes Study (UKPDS) trials have also shown benefit to tight glycemic control in type 2 diabetics. Patients with diabetes mellitus incur emergency department (ED) costs three times higher and are admitted to the hospital four times more often than nondiabetic patients.

PRINCIPLES OF DISEASE

Normal Physiology

Maintenance of the plasma glucose concentration is critical to survival because plasma glucose is the predominant metabolic fuel used by the central nervous system (CNS). The CNS cannot synthesize glucose, store more than a few minutes’ supply, or concentrate glucose from the circulation. Brief hypoglycemia can cause profound CNS dysfunction, and prolonged severe hypoglycemia may cause cellular death. Glucose regulatory systems have evolved to prevent or correct hypoglycemia.

The plasma glucose concentration is normally maintained within a relatively narrow range, between 60 and 150 mg/dL, despite wide variations in glucose levels after meals and exercise. Glucose is derived from three sources: intestinal absorption from the diet; glycolysis, the breakdown of glycogen; and gluconeogenesis, the formation of glucose from precursors, including lactate, pyruvate, amino acids, and glycerol. After glucose ingestion, the plasma glucose concentration increases as a result of glucose absorption. Endogenous glucose production is suppressed. Plasma glucose then rapidly declines to a level below the baseline.

Insulin

Insulin receptors on the beta cells of the pancreas sense elevations in blood glucose and trigger insulin release into the blood. For incompletely understood reasons, glucose taken by mouth evokes more insulin release than parenteral glucose. Certain amino acids induce insulin release and even cause hypoglycemia in some patients. Sulfonylurea oral hypoglycemic agents work, in part, by stimulating the release of insulin from the pancreas.

The number of receptor sites helps determine the sensitivity of the particular tissue to circulating insulin. The number and sensitivity of receptor sites are also the primary factors in the long-term efficacy of the sulfonylurea oral hypoglycemic agents. Receptor sites are increased in glucocorticoid deficiency and may be relatively decreased in obese patients.

Under normal circumstances, insulin is rapidly degraded through the liver and kidneys. The half-life of insulin is 3 to 10 minutes in the circulation. Whereas insulin is the major anabolic hormone pertinent to the diabetic disorder, glucagon plays the role of the major catabolic hormone in disordered glucose homeostasis.

Although most tissues have the enzyme systems required to synthesize and hydrolyze glycogen, only the liver and kidneys contain glucose-6-phosphatase, the enzyme necessary for the release of glucose into the circulation. The liver is essentially the sole source of endogenous glucose production. Renal gluconeogenesis and glucose release contribute substantially to the systemic glucose pool only during prolonged starvation.

The hepatocyte does not require insulin for glucose to cross the cell membrane. However, insulin augments both the hepatic glucose uptake and storage needed for the process of energy generation and glycogen and fat synthesis. Insulin inhibits hepatic gluconeogenesis and glycogenolysis.

Muscle can store and use glucose, primarily through glycolysis to pyruvate, which is reduced to lactate or transaminated to form alanine. Lactate released from muscle is transported to the liver, where it serves as a gluconeogenic precursor. Alanine may also flow from muscle to liver. During fasting, muscle can reduce its glucose uptake, oxidize fatty acids for its energy needs, and, through proteolysis, mobilize amino acids for transport to the liver as gluconeogenic precursors. Adipose tissue can also use glucose for fatty acid synthesis for oxidation to form triglycerides. During fasting, adipocytes can also decrease their glucose use and satisfy energy needs through the beta-oxidation of fatty acids. Other tissues do not
have the capacity to decrease glucose use on fasting and therefore produce lactate at relatively fixed rates.

Glucose transport across the fat cell membrane also requires insulin. A large percentage of the adipocyte glucose is metabolized to form α-glycerophosphate, required for the esterification of fatty acids to form triglycerides. Although most insulin-mediated fatty acid synthesis occurs in the liver, a very small percentage occurs in fat cells, using the acetyl coenzyme A generated by glucose metabolism. Very low levels of insulin are required to inhibit intracellular lipolysis while stimulating the extracellular lipolysis required for circulating lipids to enter the fat cell.

**Glucose Regulatory Mechanisms**

Maintenance of the normal plasma glucose concentration requires precise matching of glucose use and endogenous glucose production or dietary glucose delivery. The regulatory mechanisms that maintain systemic glucose balance involve hormonal, neurohumoral, and autoregulatory factors. Glucoregulatory hormones include insulin, glucagon, epinephrine, cortisol, and growth hormone. Insulin is the main glucose-lowering hormone. Insulin suppresses endogenous glucose production and stimulates glucose use. Insulin is secreted from the beta cells of the pancreatic islets into the hepatic portal circulation and has important actions on the liver and the peripheral tissues. Insulin stimulates glucose uptake, storage, and use by other insulin-sensitive tissues such as fat and muscle.4

Counter-regulatory hormones include glucagon, epinephrine, norepinephrine, growth hormone, and cortisol. When glucose is not transported into the cells because of either a lack of food intake or lack of insulin, the body perceives a “fasting state” and releases glucagon, attempting to provide the glucose necessary for brain function. In contrast to the fed state, in the fasting state the body metabolizes protein and fat. Glucagon is secreted from the alpha cells of the pancreatic islets into the hepatic portal circulation. Glucagon lowers hepatic levels of fructose 2,6-biphosphate, resulting in decreased glycolysis and increased gluconeogenesis, an effect that may be enhanced by ketosis.5 Glucagon increases the activity of adenylyl cyclase in the liver, thereby increasing glycogen breakdown to glucose and further increasing hepatic gluconeogenesis. Glucagon acts to increase ketone production in the liver. Thus, whereas insulin is an anabolic agent that reduces blood glucose, glucagon is a catabolic agent that increases blood glucose. Glucagon is released in response to hypoglycemia as well as to stress, trauma, infection, exercise, and starvation. It increases hepatic glucose production within minutes, although transiently.

Epinephrine both stimulates hepatic glucose production and limits glucose use through both direct and indirect actions mediated through both alpha- and beta-adrenergic mechanisms. Epinephrine also acts directly to increase hepatic glycogenolysis and gluconeogenesis. It acts within minutes and produces a transient increase in glucose production but continues to support glucose production at approximately basal levels thereafter. Norepinephrine exerts hyperglycemic actions by mechanisms similar to those of epinephrine, except that norepinephrine is released from axon terminals of sympathetic postganglionic neurons.

Growth hormone initially has a plasma glucose-lowering effect. Its hypoglycemic effect does not appear for several hours. Thus, growth hormone release is not critical for rapid glucose counter-regulation; this is also true for cortisol. Over the long term, both growth hormone and cortisol may also increase glucose production.

**Types of Diabetes**

The National Diabetes Data Group (NDDG) defines four major types of diabetes mellitus: type 1 diabetes mellitus, type 2 diabetes mellitus, gestational diabetes, and IGT/IFG (Box 124-1).7 The 1997 NDDG report discontinued the use of the terms “insulin-dependent diabetes mellitus” and “non-insulin-dependent diabetes mellitus” because they are confusing and clinically inaccurate. The group also recommended that Arabic numerals 1 and 2 be used to replace roman numerals I and II in the designation of types “one” and “two.”7

**Type 1 Diabetes Mellitus**

Type 1 (or I) diabetes is characterized by abrupt failure of production of insulin with a tendency to ketosis even in the basal state. Parenteral insulin is required to sustain life. From 85 to 90% of patients with type 1 diabetes demonstrate evidence of one or more autoantibodies implicated in the cell-mediated autoimmune destruction of the beta cells of the pancreas. Strong human leukocyte antigen (HLA) associations are also found in type 1 diabetes. The autoimmune destruction has multiple genetic predispositions and may be related to undefined environmental insults.7

**Type 2 Diabetes Mellitus**

Patients with type 2 (or II) diabetes may remain asymptomatic for long periods and show low, normal, or elevated levels of insulin because of insulin resistance. Ketosis is rare in type 2 disease. Patients have a high incidence of obesity. No association exists with viral infections, islet cell autoantibodies, or HLA expression. Hyperinsulinemia may be related to peripheral tissue resistance to insulin because of defects in the insulin receptor.8 Defects in muscle glycogen synthesis have an important role in the insulin resistance that occurs in type 2. A subgroup of patients who develop type 2 disease before 25 years of age have a mutation in the glucokinase gene and on chromosome 7.9
Gestational Diabetes

Gestational diabetes "mellitus" is characterized by an abnormal oral glucose tolerance test (OGTT) that occurs during pregnancy and either reverts to normal during the postpartum period or remains abnormal. The clinical presentation is thought to be similar to that of type 2. The clinical presentation is usually nonketotic hyperglycemia during pregnancy.

Impaired Glucose Tolerance

A fourth category is impaired glucose tolerance (IGT) and its analogue, impaired fasting glucose (IFG). This group is composed of persons whose plasma glucose levels are between normal and diabetic and who are at increased risk for the development of diabetes and cardiovascular disease. The pathogenesis is thought to be related to insulin resistance. Presentations of IGT/IFG include nonketotic hyperglycemia, insulin resistance, hyperinsulinism, and often obesity.

IGT/IFG differs from the other classes in that it is not associated with the same degree of complications of diabetes mellitus. Many of these patients even spontaneously develop normal glucose tolerance. The emergency physician, however, should not be complacent about the patient with IGT because the decompensation of this group into the category of diabetes mellitus is 1 to 5% per year.10,11

Epidemiology

The prevalence of diabetes is difficult to determine because many standards have been used. The NDDG, using the 75-g OGTT as the diagnostic criterion, estimates the prevalence as 6.6%, with 11.2% of the population having IGT. These figures are probably too high because most subjects diagnosed with IGT or diabetes by OGTT never develop the disease. The true prevalence of the disease is probably 6.3% of the population. Approximately 5 to 10% of these patients have type 1, and 90 to 95% have type 2. Some groups have a much higher rate of diabetes, such as the Pima Native Americans, who have a 40% rate of type 2 disease; however, diabetes mellitus is significantly more prevalent in whites than in nonwhites. The peak age of onset of type 1 diabetes is 10 to 14 years. Approximately 1 of every 600 schoolchildren has this disease. In the United States the prevalence of type 1 is approximately 0.26% by age 20 years, and the lifetime prevalence approaches 0.4%. The annual incidence among persons from birth to 16 years of age in the United States is 12 to 14 per 1 million population. The incidence is age-dependent, increasing from near-absence during infancy to a peak occurrence at puberty and another small peak at midlife.

The morbidity in diabetes is related mostly to its vascular complications. A mortality rate of 36.8% has been related to diabetic comas, and 12.5% to renal failure.

Pathophysiology and Etiology

Type 1 diabetes results from a chronic autoimmune process that usually exists in a preclinical state for years. The classical manifestations of type 1—hyperglycemia and ketosis—occur late in the course of the disease, an overt sign of beta-cell destruction.

The most striking feature of long-standing type 1 diabetes is the near-total lack of insulin-secreting beta cells and insulin, with the preservation of glucagon-secreting alpha cells, somatostatin-secreting delta cells, and pancreatic polypeptide-secreting cells.

Although the exact cause of diabetes remains unclear, research has provided many clues. Studies of the pathogenesis of diabetes mellitus have demonstrated that the cause of the disordered glucose homeostasis varies from individual to individual. This may determine the presentation in each patient. Individual patients are currently not studied for the source of their disease except on an experimental basis. The goals of the work in progress, however, are to identify who is susceptible to the development of diabetes and to prevent diabetic emergencies and sequelae or to prevent expression of the disease.

A genetic basis for diabetes is suggested by the association of type 1 disease with certain HLA markers and by the findings of numerous twin and family studies. Families who move from areas with a low frequency of type 1 diabetes to areas with a high frequency have an incidence of disease similar to that in the areas where they reside; this suggests an environmental basis for diabetes. An autoimmune cause has been clearly demonstrated in many type 1 diabetic patients. Islet cell myeloid has also been associated with diabetes. In both types, a variety of viruses have been implicated, most notably congenital rubella, coxsackievirus B, and cytomegalovirus.

Research has identified two groups of cellular carbohydrate transporters in cell membranes. Sodium-linked glucose transporters are found primarily in the intestine and kidney. The glucose transporter (GLUT) proteins are found throughout the body and transport glucose by facilitated diffusion down concentration gradients. The GLUT-4 transporter, found primarily in muscle, is insulin-responsive, and a signaling defect in the protein may be responsible for insulin resistance in some diabetic patients.

</table>

The patient with type 1 diabetes is usually lean, younger than 40 years of age, and ketosis-prone. Plasma insulin levels are absent to low; plasma glucagon levels are high but suppressible with insulin, and patients require insulin therapy when symptoms appear. Onset of symptoms may be abrupt, with polydipsia, polyuria, polyphagia, and weight loss developing rapidly. In some cases the disease is heralded by ketoacidosis. A myriad of problems related to type 1 diabetes may prompt an ED visit, including acute metabolic complications such as DKA and late complications such as cardiovascular or circulatory abnormalities, retinopathy, nephropathy, neuropathy, foot ulcers, severe infections, and various skin lesions.

Type 2

The patient with type 2 diabetes is usually middle-aged or older, overweight, with normal to high insulin levels. Insulin levels are lower than would be predicted for glucose levels, however, leading to a relative insulin deficiency, probably because of an insulin secretory defect. All type 2 patients demonstrate impaired insulin function related to poor insulin production, failure of insulin to reach the site of action, or failure of end-organ response to insulin.

As with type 1 diabetes, research suggests distinct subgroups of patients fall within the classification of type 2 diabetes. Although most adult patients are obese, 20% are not. Non-obese patients form a subgroup with a different disease, more similar to type 1. Another subgroup comprises young persons with maturity-onset diabetes. They have an autosomal dominant inheritance of their disease, are usually not obese, and have a relatively mild course of disease.
Symptoms tend to begin more gradually in type 2 diabetes than in type 1. The diagnosis of type 2 is often made because of an elevated blood glucose found on routine laboratory examination. Glucose may be controlled by dietary therapy, oral hypoglycemic agents, or insulin administration, depending on the individual. Decompensation of disease usually leads to hyperosmolar nonketotic coma rather than ketosis.

Type 2 diabetes is increasingly being diagnosed in children and adolescents.19

### Diagnostic Strategies

#### Serum Glucose

As a rule, any random plasma glucose level greater than 200 mg/dL, a fasting plasma glucose concentration greater than 126 mg/dL, or a 2-hour postload OGTT is sufficient to establish the diagnosis of diabetes. In the absence of hyperglycemia with metabolic decompensation, these criteria should be confirmed by repeat testing on a different day.2 A value of 150 mg/dL is likely to distinguish diabetic from nondiabetic patients more accurately. Formal OGTTs are unnecessary except during pregnancy or in patients who are thought to have diabetes but who do not meet the criteria for a particular classification. The World Health Organization and NDDG have different implications about urine glucose concentration of the preceding 6 to 8 weeks, with normal values approximately 4 to 6% of total hemoglobin, depending on the assay used. Levels in patients with poorly controlled disease may reach 10 to 12%. Measurement of glycated albumin can be used to monitor diabetic control over 1 to 2 weeks because of its short half-life but is rarely used clinically. The American Diabetes Association (ADA) recommends at least biannual measurements of HbA1c for the follow-up of all types of diabetes. The ADA currently sets an HbA1c of less than 7% as a treatment goal.

#### Glycosylated Hemoglobin

Measurement of glycosylated hemoglobin (HbA1c) is one of the most important ways to assess the level of glucose control. Elevated serum glucose binds progressively and irreversibly to the amino-terminal valine of the hemoglobin beta-chain. The HbA1c measurement provides insight into the quality of glycemic control over time. Given the long half-life of red blood cells, the percentage of HbA1c is an index of glucose concentration of the preceding 6 to 8 weeks, with normal values approximately 4 to 6% of total hemoglobin, depending on the assay used. Levels in patients with poorly controlled disease may reach 10 to 12%. Measurement of glycated albumin can be used to monitor diabetic control over 1 to 2 weeks because of its short half-life but is rarely used clinically. The American Diabetes Association (ADA) recommends at least biannual measurements of HbA1c for the follow-up of all types of diabetes. The ADA currently sets an HbA1c of less than 7% as a treatment goal.

#### Urine Glucose

Urine glucose measurement methods are basically of two types: reagent tests and dipstick tests. The reagent tests (e.g., Clinitest) are copper reduction tests. They are somewhat more cumbersome and expensive than dipstick methods, use tablets that are very caustic and dangerous if accidentally ingested, and may be affected by many substances (Box 124-2). Dipstick tests generally use glucose oxidase, which may also be affected by different substances (Box 124-3). Dipsticks are inexpensive and convenient but may vary in their sensitivity and strength of reaction to a given concentration of glucose. Dipstick interpretation can vary significantly, depending on the observer and the type of lighting. Both falsely high and falsely low urine glucose readings can also occur. With the “plus” system, one-plus, two-plus, three-plus, and four-plus have different implications about urine glucose concentrations, depending on the brand of dipstick. Using reflectance colorimeters to read dipsticks increases accuracy. Urine glucose tests must be interpreted loosely because many factors can affect their results.

#### Urine Ketones

Urine ketone dipsticks use the nitroprusside reaction, which is a good test for acetoacetate but does not measure β-hydroxybutyrate. Although the usual acetoacetate/β-hydroxybutyrate ratio in diabetic ketoacidosis is 1:2.8, it may be as high as 1:30, in which case the urine dipstick does not reflect the true level of ketosis. When ketones are in the form of β-hydroxybutyrate, the urine ketone dipsticks may infrequently yield negative reactions in patients with significant ketosis.

From Contemp Pharm Pract 3:224, 1980.
Dipstick Blood Glucose

Dipsticks for testing blood glucose are clearly a more accurate means of monitoring blood glucose than urine dipsticks but also may be inaccurate. Hematocrits below 30% or above 55% cause unduly high or low readings, respectively, and a number of the strips specifically disclaim accuracy when used for neonates. Sensitivity of dipsticks to a variety of factors varies with the particular brand. The largest errors are in the hyperglycemic range. Dipstick readings rarely err more than 30 mg/dL when actual concentrations are below 90 mg/dL. Although specific glucose concentrations may not be accurately represented, blood glucose dipsticks are useful in estimating the general range of the glucose value. Reflectance meters increase the accuracy of the dipstick blood glucose determination. If maximum accuracy is desired, a laboratory blood glucose level should be obtained.

HYPOGLYCEMIA

Hypoglycemia is a common problem in patients with type 1 diabetes, especially if tight glycemic control is practiced, and may be the most dangerous acute complication of diabetes. The estimated incidence of hypoglycemia in diabetic patients is 9 to 120 episodes per 100 patient-years. As significant efforts continue to keep both fasting and postprandial glucose within the normal range, the incidence of hypoglycemia may increase. The most common cause of coma associated with diabetes is an excess of administered insulin with respect to glucose intake. Hypoglycemia may be associated with significant morbidity and mortality. Severe hypoglycemia is usually associated with a blood sugar level below 40 to 50 mg/dL and impaired cognitive function.

Principles of Disease

Protection against hypoglycemia is normally provided by cessation of insulin release and mobilization of counter-regulatory hormones, which increase hepatic glucose production and decrease glucose use. Diabetic patients using insulin are vulnerable to hypoglycemia because of insulin excess and failure of the counter-regulatory system. Hypoglycemia may be caused by missing a meal, increasing energy output, or increasing insulin dosage. It can also occur in the absence of any precipitant (Box 124-4). Oral hypoglycemic agents have also been implicated in causing hypoglycemia, both in the course of therapy and as an agent of overdose. Hypoglycemia without warning, or hypoglycemia unawareness, is a dangerous complication of type 1 diabetes probably caused by previous exposure to low blood glucose concentrations. Even a single hypoglycemic episode can reduce neurohumoral counter-regulatory responses to subsequent episodes. Other factors associated with recurrent hypoglycemic attacks include overaggressive or intensified insulin therapy, longer history of diabetes, autonomic neuropathy, and decreased epinephrine secretion or sensitivity.

The Somogyi phenomenon is a common problem associated with iatrogenic hypoglycemia in the type 1 diabetic patient. The phenomenon is initiated by an excessive insulin dosage that results in an unrecognized hypoglycemic episode that usually occurs in the early morning while the patient is sleeping. The counter-regulatory hormone response produces rebound hyperglycemia, evident when the patient awakens. Often, both the patient and the physician interpret this hyperglycemia as an indication to increase the insulin dosage, which exacerbates the problem. Instead, the insulin dosage should be lowered or the timing changed.

Clinical Features

Symptomatic hypoglycemia occurs in most adults at a blood glucose level of 40 to 50 mg/dL. The rate at which glucose decreases, however, as well as the patient’s age, gender, size, overall health, and previous hypoglycemic reactions all contribute to symptom development. Signs and symptoms of hypoglycemia are caused by excessive secretion of epinephrine and CNS dysfunction and include sweating, nervousness, tremor, tachycardia, hunger, and neurologic symptoms ranging from bizarre behavior and confusion to seizures and coma.

In patients with hypoglycemia unawareness, the prodrome to marked hypoglycemia may be minimal or absent. These individuals may rapidly become unarousable without warning. They may have a seizure or show focal neurologic signs, which resolve with glucose administration.

Diagnostic Strategies

The cardinal laboratory test for hypoglycemia is blood glucose. It should be obtained, if possible, before therapy is begun. As noted, dipstick readings are very helpful in permitting rapid, reasonably accurate blood glucose estimates before therapy.

Laboratory testing should address any suggested cause of the hypoglycemia, such as ethanol or other drug ingestion. If factitious hypoglycemia is suggested, testing for insulin antibodies or low levels of C peptide may be helpful. A patient who is surreptitiously administering exogenous insulin will have normal to low levels of C peptide and markedly elevated insulin levels.

- Sepsis
- Some antibacterial sulfonylureas
- Worsening renal insufficiency
Management

In alert patients with mild symptoms, oral consumption of sugar-containing foods or beverages is often adequate (Box 124-5). In other patients, after blood is drawn for glucose determination, one to three ampules of 50% dextrose in water (D50W) should be administered intravenously while the patient's airway, breathing, and circulation are assessed and maintained. Augmentation of the blood glucose level by administering an ampule of D50W may range from less than 40 to more than 350 mg/dL.30 These therapeutic steps are appropriately performed in the field if out-of-hospital care is available. If alcohol abuse is suggested, thiamine should also be administered. D50W should not be used in infants or young children because venous sclerosis can lead to rebound hypoglycemia. In a child younger than 8 years it is advisable to use 25% (D25W) or even 10% dextrose (D10W). D25W may be pre pared by diluting D50W 1:1 with sterile water. The dose is 0.5 to 1 g/kg body weight or, using D50W, 2 to 4 mL/kg.

If intravenous (IV) access cannot be rapidly obtained, 1 to 2 mg of glucagon may be given intramuscularly or subcutaneously.31 1 The onset of action is 10 to 20 minutes, and peak response occurs in 30 to 60 minutes. It may be repeated as needed. Glucagon may also be administered intravenously; 1 mg has an effect very similar to that of one ampule of D50W. Glucagon is ineffective in causes of hypoglycemia in which glycogen is absent, notably alcohol-induced hypoglycemia.

Families of type 1 diabetic patients are often taught to administer intramuscular glucagon at home. Of the families so instructed, only 9 to 42% actually inject the glucagon when indicated.32 Intranasal glucagon may become more widely accepted.33 Out-of-hospital care providers and emergency physicians should seek a history of glucagon administration because it alters initial blood glucose readings.

All patients with severe hypoglycemic reactions require aspiration and seizure precautions. Although the response to IV glucose is generally rapid, older patients may require several days for complete recovery.

Oral hypoglycemic agents pose special problems because the hypoglycemia they induce tends to be prolonged and severe. There are isolated case reports in which hypogly cemia was delayed in onset by as much as 24 hours and occurred more than 72 hours later. Chlorpropamide is particularly troublesome in this respect. Thus, patients with overdose of oral hypoglycemic agents should have a minimum observation period of 24 hours and longer if hypoglycemia is recurrent.

Patients at risk for hypoglycemia from oral sulfonylureas include patients with impaired renal function; pediatric patients; and patients who are naive to hypoglycemic agents. Although symptoms may occur after an overdose, in patients with renal failure and pediatric patients, refractory hypoglycemia has been reported with a single pill.

Treatment of hypoglycemia secondary to oral hypoglycemic agents depends on the agent. Metformin and the thiazolidinedione agents rarely cause significant or prolonged hypoglycemia, whereas sulfonylureas, which are insulin secretagogues, do cause hypoglycemia. A patient with hypoglycemia from sulfonylureas, in addition to standard glucose replacement, frequently requires treatment with an agent to inhibit further insulin release, such as octreotide, a somatostatin analogue. Several case series reporting the use of octreotide in both adult and pediatric patients suffering from sulfonylurea-induced hypoglycemia have been described, frequently reporting successful results with a significant decrease in the number of episodes of recurrent hypoglycemia.34,35 No single set protocol for their use has been described; however, typical adult doses have ranged from 50 to 100 µg IV or SQ every 12 hours and pediatric dosages of 25 to 50 µg IV or SQ. Data on the use of octreotide is promising though it does not obviate the need for prolonged observation and serial glucose measurements.

When therapy for hypoglycemia has been given, a careful history must be taken to determine the cause.

Disposition

Type 1 diabetic patients with brief episodes of hypoglycemia uncomplicated by other disease may be discharged from the ED if a cause of the hypoglycemia can be identified and corrected by instruction or medication. All patients should be given a meal before discharge to ensure their ability to tolerate oral feedings and to begin to replenish glycogen stores in glycogen-deficient patients. Patients who are discharged should receive short-term follow-up for ongoing evaluation. Patients with hypoglycemia caused by oral agents should be observed in the hospital because of the high likelihood of recurrent hypoglycemia.

Nondiabetic Patients

Hypoglycemia in the nondiabetic patient may be classified as postprandial or fasting (Box 124-6). The most common cause of postprandial hypoglycemia is alimentary hyperinsulinism, such as that seen in patients who have undergone gastrectomy, gastrojejunoscopy, pyloroplasty, or vagotomy. Fasting hypogly cemia is caused when there is an imbalance between glucose production and use. The causes of inadequate glucose production include hormone deficiencies, enzyme defects, substrate deficiencies, severe liver disease, and drugs. Causes of overuse of glucose include the presence of an insulinoma, exogenous insulin, sulfonylureas, drugs, endotoxic shock, extrapancreatic tumors, and a variety of enzyme deficiencies.

Emergency treatment is similar to that of hypoglycemia in the diabetic patient. The determination of inpatient versus outpatient evaluation of hypoglycemia in a nondiabetic patient should be based on the suggested cause and the nature of the episode (i.e., factors such as severity, persistence, and recurrence).

### DIABETIC KETOACIDOSIS

#### Principles of Disease

**Pathophysiology**

DKA is a syndrome in which insulin deficiency and glucagon excess combine to produce a hyperglycemic, dehydrated, acidic patient with profound electrolyte imbalance (Fig. 124-1). All derangements producing DKA are interrelated and are based on insulin deficiency. DKA may be caused by cessation of insulin intake or by physical or emotional stress despite continued insulin therapy.

The effects of insulin deficiency may be mimicked in peripheral tissues by a lack of either insulin receptors or insulin sensitivity at receptor or postreceptor sites. When the hyperglycemia becomes sufficiently marked, the renal threshold is surpassed and glucose is excreted in the urine. The hyperosmolarity produced by hyperglycemia and dehydration is the most important determinant of the patient’s mental status.

Glucose in the renal tubules draws water, sodium, potassium, magnesium, calcium, phosphorus, and other ions from the circulation into the urine. This osmotic diuresis combined with poor intake and vomiting produces the profound dehydration and electrolyte imbalance associated with DKA (Table 124-1). Exocrine pancreatic dysfunction closely parallels endocrine beta-cell dysfunction, producing malabsorption that further limits the body’s intake of fluid and exacerbates electrolyte loss.

In 95% of patients with DKA, the total sodium level is normal or low. Potassium, magnesium, and phosphorus deficits

Diagnostic Strategies

History

Clinically, most patients with DKA complain of a recent history of polydipsia, polyuria, polyphagia, visual blurring, weakness, weight loss, nausea, vomiting, and abdominal pain. Approximately one half of these patients, especially children, report abdominal pain. In children this pain is usually idiopathic and probably caused by gastric distention or stretching of the liver capsule; it resolves as the metabolic abnormalities are corrected. In adults, however, abdominal pain more often signifies true abdominal disease.

Physical Examination

Physical examination may or may not demonstrate a depressed sensorium. Typical findings include tachypnea with Kussmaul’s respiration, tachycardia, frank hypotension or orthostatic blood pressure changes, the odor of acetone on the breath, and signs of dehydration. An elevated temperature is rarely caused by DKA itself and suggests the presence of infection.

Laboratory Tests

Initial tests allow preliminary confirmation of the diagnosis and immediate initiation of therapy (Table 124-2). Subsequent tests are made to determine more specifically the degree of dehydration, acidosis, and electrolyte imbalance and to reveal the precipitant of DKA.

On the patient’s arrival to the ED, serum and urine glucose and ketones, electrolytes, and arterial blood gases (ABGs) should be checked. Glucose is usually elevated above 350 mg/dL; however, euglycemic DKA (blood glucose < 300 mg/dL) has been reported in up to 18% of patients.4 ABGs demonstrate a low pH. Venous pH is not significantly different from arterial pH in patients with DKA, and some researchers con-
sider the use of venous blood superior to repeated arterial puncture. Metabolic acidosis with an anion gap is primarily the result of elevated plasma levels of acetoacetate and β-hydroxybutyrate, although lactate, FFAs, phosphates, volume depletion, and several medications also contribute to this condition. Rarely, a well-hydrated patient with DKA may have a pure hyperchloremic acidosis with no anion gap. If an immediate potassium level is not available through ABG, an electrocardiogram may indicate potassium levels. Despite initial potassium levels that are normal to high, a total potassium deficit of several hundred milliequivalents results from potassium and hydrogen shifts.

Other tests may include complete blood count with differential, magnesium, calcium, amylase, blood urea nitrogen (BUN), creatinine, phosphorus, ketone, and lactate level determinations. A complete urinalysis helps in the determination of possible infection or renal disease. Elevations of urine specific gravity, BUN, and hematocrit suggest dehydration. Appropriate cultures should be dictated by clinical findings.

The serum sodium value is often misleading in DKA. Sodium is often low in the presence of significant dehydration because it is strongly affected by hyperglycemia; hypertriglyceridemia; salt-poor fluid intake; and increased GI, renal, and insensible losses. When hyperglycemia is marked, water flows from the cells into the vessels to decrease the osmolar gradient, thereby creating dilutional hyponatremia. Lipids also dilute the blood, thereby further lowering the value of sodium. Newer autoanalyzers remove triglycerides before assay, thus eliminating this artifact.

Hypertriglyceridemia is common in DKA because of impaired lipoprotein lipase activity and hepatic overproduction of very-low-density lipoproteins. In the absence of marked lipidemia, the true value of sodium may be approximated by adding 1.3 to 1.6 mEq/L to the sodium value on the laboratory report for every 100 mg/dL glucose over the norm. Thus, if the laboratory reports a serum sodium value of 130 mEq/L and a blood glucose value of 700 mEq/L, the total serum sodium value is more accurately assessed to be between 137.8 and 139.6 mEq/L.

Acidosis and the hyperosmolarity induced by hyperglycemia shift potassium, magnesium, and phosphorus from the intracellular to the extracellular space. Dehydration produces hemoconcentration, which contributes to normal or high initial serum potassium, magnesium, and phosphorus readings in DKA, even with profound total body deficits. The effect of acidosis on the serum potassium determination can be corrected by subtracting 0.6 mEq/L from the laboratory potassium value for every 0.1 decrease in pH noted in the ABG analysis. Thus, if the potassium is reported as 5 mEq/L and the pH is 6.94, the corrected potassium value would be only 2 mEq/L, representing severe hypokalemia. While insulin is administered and the hydrogen ion concentration decreases, the patient needs considerable potassium replacement. Finally, hyperglycemia and the anion gap have significant effects on the plasma potassium concentration, independent of acidosis.

No conversion factor has been developed for estimating true magnesium levels, although initial values may be high.

All laboratory determinations must be interpreted with caution. Serum creatinine determinations made by autoanalyzer may be falsely elevated. Leukocytosis more closely reflects the degree of ketosis than the presence of infection. Only the elevation of band neutrophils has been demonstrated to indicate the presence of infection, with a sensitivity of 100% and a specificity of 80%. The diagnosis of pancreatitis is confirmed by the usually elevated urine and serum amylase levels in DKA. Typically, this is salivary amylase, but most laboratories are not equipped to make this distinction. A serum lipase determination helps to distinguish pancreatitis from elevated salivary amylase levels.

### Differential Considerations

Alcoholics, especially those who have recently abstained from drinking, with Kussmaul’s respiration, a fruity odor to the breath, and acidemic ABG values may have alcoholic ketoacidosis. These patients may be euglycemic or hypoglycemic, and a large part of their acidosis is often caused by the unmeasured β-hydroxybutyric acid. Alcoholic ketoacidosis accounts for approximately 20% of all cases of ketoacidosis.

Ketoacidosis can also develop with fasting in the third trimester of pregnancy and in nursing mothers who do not eat.

Other entities that may manifest with various combinations of altered mental status, acidosis, and abdominal pain include hypoglycemia, cerebrovascular accident (stroke), trauma, sepsis, hyperglycemic hyperosmolar nonketotic coma, postictal states, lactic acidosis, uremic acidosis, and abdominal emergencies. Intoxications by ethanol, salicylates, methanol, isopropyl alcohol, chloral hydrate, paraldehyde, ethylene glycol, and cyanide all share some features of DKA.

### Management

#### General Measures

The approach to the patient with severe DKA is the same as that to any patient in extremis. The comatose patient, especially if vomiting, requires intubation. Once the patient is intubated, hyperventilation should be maintained to prevent worsening acidosis. The patient in hypovolemic shock requires aggressive fluid resuscitation with 0.9% saline solution rather than pressors. Other possible causes of shock (e.g., sepsis or myocardial dysfunction secondary to MI) should be considered. Close monitoring of vital signs is essential. In the patient whose therapy may precipitate fluid overload caused by cardiac compromise or renal failure, a central venous pressure line or Swan-Ganz catheter should be inserted.

The diagnosis of DKA is generally simple. When hyperglycemia, ketosis, and acidosis have been established, fluid, electrolyte, and insulin therapy should begin (Box 124-7).

#### Insulin

DKA cannot be reversed without insulin, and insulin therapy should be initiated as soon as the diagnosis is certain. In the past, very high dosages of insulin were administered to diabetic patients in DKA because they were thought to be extremely insulin-resistant. However, low-dosage insulin therapy has proved as effective as high-dosage therapy. The rate of decrease in blood sugar is equal or only slightly more gradual. The overall potassium requirement is less. High dosages of insulin have potentially harmful effects, including a greater incidence of iatrogenic hypoglycemia and hypokalemia.

The exact amount of insulin administered varies. Many start therapy with a bolus of 10 U of regular insulin intravenously. This initial bolus may produce certain problems, however, and makes no significant difference in therapy. The current therapy of choice is regular insulin infused at 0.1 U/kg/hr up to 5 to 10 U/kg/hr, mixed with the IV fluids. Regular insulin, 10 to 20 U/hr, administered intramuscularly accomplishes similar effects but subjects the patient to repeated painful injections. In theory, intramuscular insulin may accumulate at a poorly perfused administration site, failing to enter the systemic circulation in a timely manner.
In children, the IV dosage of regular insulin may be calculated at 0.1 U/kg. Children are more likely than adults to develop cerebral edema in response to a rapid lowering of plasma osmolarity. Thus, reduction of glucose levels in children should be gradual.

Because the half-life of regular insulin is 3 to 10 minutes, IV insulin should be administered by constant infusion rather than by repeated bolus. When the blood glucose has dropped to 250 to 300 mg/dL, dextrose should be added to the IV fluids to prevent iatrogenic hypoglycemia and cerebral edema. In patients with euglycemic DKA, dextrose should be added to the IV fluids at the start of insulin therapy.

Insulin adheres to the walls of glass and polyvinyl bottles and tubing, making the exact amount of insulin being administered uncertain. Running approximately 10 U of the insulin infusion through the tubing accomplishes adherence without altering the delivered concentration of the remainder of the infusate.

The severely dehydrated patient is likely to have a fluid deficit of 3 to 5 L. No uniformly accepted formula exists for the administration of fluid in this disorder.

If the patient is in hypovolemic shock, normal saline (NS) should be administered as rapidly as possible in the adult, or in 20 mL/kg boluses in the child, until a systolic pressure of 80 mm Hg is obtained. In the adult who has marked dehydration in the absence of clinical shock or heart failure, 1 L of NS may be administered in the first hour. In general, 2 L of NS over the first 1 to 3 hours is followed by a slower infusion of half-NS solution. Patients with DKA without extreme volume depletion may be successfully treated with a lower volume of IV fluid replacement. NS solution at 20 mL/kg over the first hour is the usual fluid resuscitation therapy for a child. Thereafter, fluid rate should be adjusted according to age, cardiac status, and degree of dehydration to achieve a urine output of 1 to 2 mL/kg/hr. Whereas some authors advocate half-NS or colloid solution, most evidence and practice favor initial resuscitation with 0.9% NS solution.

Fluid resuscitation alone may help to lower hyperglycemia. Because even in DKA a low level of circulating insulin may be present, increased perfusion may transport insulin to previously unreached receptor sites. In addition, a large volume of glucose may be cleared by the kidneys in response to improved renal perfusion. The mean plasma glucose concentration has been noted to drop 18% after administration of saline solution without insulin.

Acidosis also decreases after fluid infusion alone. Increased perfusion improves tissue oxygenation, thus diminishing the formation of lactate. Increased renal perfusion promotes renal hydrogen ion loss, and the improved action of insulin in the better-hydrated patient inhibits ketogenesis.

Some authors believe that the rapid decrease of the hyperosmolarity of DKA caused by the administration of 0.45% NS solution may precipitate cerebral edema, one of the most dangerous complications associated with the patient in DKA, especially children.

**Potassium**

Potassium replacement is invariably needed in DKA. The initial potassium level is often normal or high despite a large deficit because of severe acidosis. Potassium levels often plummet with correction of acidosis and administration of insulin. Potassium should be administered with the fluids while the laboratory value is in the upper half of the normal range. Renal function should be monitored. In patients with low serum potassium at presentation, hypokalemia may become life-threatening when insulin therapy is administered.
IV potassium should be vigorously administered in concentrations of 20 to 40 mEq/L as required.

Some clinicians administer a portion of the potassium as the phosphate salt. In DKA, phosphate falls from a mean value of 9.2 to 2.8 mg/dL within 12 hours of therapy, reflecting an average total deficit of 0.5 to 1.5 mmol/kg. This may result in a decreased level of 2,3-diphosphoglycerate (2,3-DPG) and subsequent poor oxygen delivery to red blood cells. Other problems associated with the hypophosphatemia are depressed myocardial and respiratory muscle performance, hemolysis, impaired phagocytosis, thrombocytopenia, platelet dysfunction, confusion, and disorientation. The platelet dysfunction is caused by therapy or is simply a manifestation of the basic pathophysiology of DKA.

6. Patients treated with bicarbonate fare no better and possibly fare worse than patients treated without bicarbonate. Studies indicate that bicarbonate worsens the prognosis even in patients with severe acidosis and pH values in the range 6.9 to 7.1. It is possible to manage severe DKA with fluids and insulin alone. When this is done, pH normalization is similar to that in a bicarbonate control group.

When bicarbonate therapy is deemed necessary, the pH should not be corrected above 7.1. Response to therapy should be followed initially with hourly vital signs; fluids should be administered and urine output measured; insulin should be given; and glucose, pH, and anion gap measurements taken. Plasma bicarbonate may remain low even while pH increases and anion gap narrows because of the hyperchloremia that develops from rapid saline infusion, loss of bicarbonate in the urine as ketones, and exchanges with intracellular buffers.

Complications

The precipitating causes of DKA may have associated morbidity and mortality rates equal to or worse than those for DKA itself. These include iatrogenic causes as well as infection and MI. Morbidity in DKA is largely iatrogenic: (1) hypokalemia from inadequate potassium replacement, (2) hypoglycemia from inadequate glucose monitoring and failure to replenish glucose in IV solutions when serum glucose drops below 250 to 300 mg/dL, (3) alkalosis from overaggressive bicarbonate replacement, (4) congestive heart failure from overaggressive hydration, and (5) cerebral edema probably caused by too rapid osmolar shifts. DKA is responsible for 70% of diabetes-related deaths in children. Poor prognostic signs include hypotension, azotemia, coma, and underlying illness.

The mortality rate in treated DKA decreased from approximately 38% between 1930 and 1959 to about 5% to 7% in the 1980s. The primary causes of death remain infection (especially pneumonia), arterial thromboses, and shock. The decrease in mortality rate demonstrates that appropriate therapy can make a difference.

Cerebral edema should be considered when the patient remains comatose or lapses into coma after the reversal of acidosis. It generally occurs 6 to 10 hours after the initiation of therapy. There are no warning signs, and the associated mortality rate is currently 90%. Cerebral edema has been associated with low partial pressures of arterial carbon dioxide, high BUN concentration, and the use of bicarbonate. Subclinical cerebral edema in children is probably very common. Furthermore, subclinical cerebral edema may either precede or follow the onset of therapy, raising the question of whether this entity is caused by therapy or is simply a manifestation of the basic pathophysiology of DKA.

Because clinically evident cerebral edema does not usually occur unless the blood sugar level is below 250 mg/dL and insulin is being used, insulin may directly antagonize the brain’s defenses against fluid shifts while the plasma glucose level approaches normal values. Other theories attribute the formation of cerebral edema to (1) “idiogenic osmols” developed in the brain as a result of insulin therapy, (2) the rate of fluid administration, and (3) the rate of correction of the acidosis. Other less common causes have been suggested. Several authors recommend the administration of mannitol, 0.25 to 2 mg/kg, at the first sign of altered mental status in children being treated for DKA. Steroids are ineffective treatment for cerebral edema secondary to DKA and may worsen DKA.
Disposition

Most patients with DKA require hospital admission, often to the intensive care unit. All pregnant diabetic patients in DKA require admission and consultation with an endocrinologist and obstetrician specializing in the care of high-risk pregnancies. Some children (initial pH > 7.35, bicarbonate ≥ 20 mEq/L) with resolution of findings who can tolerate oral fluids after 3 or 4 hours of treatment may be discharged home with a reliable caregiver. Patients who have mild DKA may be treated on an outpatient basis if (1) the patient or parent is reliable, (2) the underlying causes do not require inpatient therapy, and (3) close follow-up is pursued.

Hyperglycemic hyperosmolar nonketotic coma (HHNC)

Hyperglycemic hyperosmolar nonketotic coma (HHNC) represents a syndrome of acute diabetic decompensation characterized by marked hyperglycemia, hyperosmolarity, and dehydration, and decreased mental function that may progress to frank coma. Ketosis and acidosis are generally minimal or absent. Focal neurologic signs are common. DKA and HHNC may occur together; some even consider HHNC to be at two ends of a spectrum, with many patients in the middle.

Principles of Disease

Pathophysiology

As with DKA, the pathophysiology of HHNC varies with the particular patient. Because most patients with HHNC are elderly, decreased renal clearance of glucose produced by the decline of renal function with age often contributes to the illness. As with DKA, decreased insulin action results in glycogenolysis, gluconeogenesis, and decreased peripheral uptake of glucose. The hyperglycemia pulls fluid from the intracellular space into the extracellular space, transiently maintaining adequate perfusion. Soon, however, this fluid is lost in a profound osmotic diuresis, limited finally by hypotension and a subsequent drop in the glomerular filtration rate (GFR). The urine is extremely hypotonic, with a urine sodium concentration between 50 and 70 mEq/L, compared with 140 mEq/L in extracellular fluid. This hypotonic diuresis produces profound dehydration, leading to hyperglycemia, hypernatremia, and associated hyperoncoticity. Often the patient is prevented from taking in adequate fluids by stroke, Alzheimer’s disease, or other diseases, greatly exacerbating the dehydration of renal origin.

The reason for the absence of ketoacidosis in HHNC is unknown. FFA levels are lower than in DKA, thus limiting substrates needed to form ketones. The most likely reason for the blunted counter-regulatory hormone release and lack of ketosis seems to be that these patients continue to secrete the tiny amount of insulin required to block ketogenesis.

Etiology

HHNC is a syndrome of severe dehydration that results from a sustained hyperglycemic diuresis under circumstances in which the patient is unable to drink sufficient fluids to offset the urinary losses. The full-blown syndrome does not usually occur until volume depletion has progressed to the point of decreased urine output.

HHNC is most common in elders with type 2 diabetes but has been reported in children with type 1 diabetes.

Box 124-8 lists the broad range of predisposing factors. HHNC may occur in patients who are not diabetic, especially after burns, parenteral hyperalimentation, peritoneal dialysis, or hemodialysis.

Clinical Features

The prodrome of HHNC is significantly longer than that of DKA. Clinically, extreme dehydration, hyperosmolarity, volume depletion, and CNS findings predominate. If awake, patients may complain of fever, thirst, polyuria, or oliguria. Approximately 20% of patients have no known history of type 2 diabetes. The most common associated diseases are chronic renal insufficiency, gram-negative pneumonia, GI bleeding, and gram-negative sepsis. Of these patients, 85% have underlying renal or cardiac impairment as a predisposing factor. Arterial and venous thromboses often complicate the picture.

The patient often exhibits orthostatic hypotension or frank hypotension, tachycardia, and fever with signs of marked dehydration. On average, the HHNC patient has a 24% fluid deficit, or 9 L in the 70-kg patient. The depression of the sensorium correlates directly with the degree and rate of development of hyperosmolarity. Some patients have normal mental status. Seizures are usually associated with neurologic findings, especially epilepsy partialis continua (continuous focal seizures) and intermittent focal motor seizures. Stroke and hemiplegia are also common. Less common neurologic findings include choreoathetosis, ballismus, dysphagia,
segmental myoclonus, hemiparesis, hemianopsia, central hyperpyrexia, nystagmus, visual hallucinations, and acute quadriplegia.

**Diagnostic Strategies**

Laboratory findings usually reveal a blood glucose level greater than 600 mg/dL and serum osmolality greater than 350 mOsm/L. The BUN concentration is invariably elevated (see Table 124-2). Although patients with HHNC do not have a ketoacidosis caused by diabetes, they may have a metabolic acidosis secondary to some combination of lactic acidosis, starvation ketosis, and retention of inorganic acids attributable to renal hypoperfusion.

The patient with HHNC typically manifests more profound electrolyte imbalance than the patient with DKA. Levels of potassium, magnesium, and phosphorus may seem initially high, even in the presence of marked total deficit. In the absence of acidaemia, however, the discrepancy between the initial electrolyte reading and body stores is less than that of DKA. Initial serum sodium readings are inaccurate because of hyperglycemia.

**Differential Considerations**

The differential diagnosis of HHNC is identical to that for DKA. In addition, diabetic patients receiving chlorpropamide are subject to water intoxication with dilutional hyponatremia, which may manifest as coma without acidosis that is clinically indistinguishable from HHNC. The patient with HHNC who has a sharply depressed sensorium may not be initially distinguishable from the patient with profound hypoglycemia. When blood glucose cannot be rapidly checked, the immediate administration of one ampule of D$_5$W minimally worsens HHNC and may be lifesaving for patients with hypoglycemia.

**Management**

The fluid, electrolyte, and insulin regimens for the initial resuscitation in HHNC are subject to the same controversies as the therapies for DKA (Box 124-9). Whereas some physicians use half-NS solution rapidly infused, most use NS solution, switching to half-NS later in the resuscitation. Just as in DKA, overly rapid correction of serum osmolality may predispose to the development of cerebral edema in children. There are few reports of cerebral edema complicating HHNC in adults.

**Dehydration**

Under central venous or pulmonary artery pressure monitoring, rapid administration of NS in a similar fashion to initial therapy for DKA is generally safe. For patients in coma or hypovolemic shock, initial IV fluid infusion should be given as rapidly as possible. If the patient does not have central monitoring and is not in coma or shock, vigorous IV fluid administration, such as 1 L/hr, is prudent and provides sufficient rehydration. In any circumstance, after 2 to 3 L of NS, 0.45% NS solution should be substituted. As the fluid deficits and hyperosmolality are corrected, the infusion rate must be slowed and electrolytes managed. In patients with concomitant congestive heart failure, sterile water has been successfully administered by central venous line at a rate of 500 mL/hr, with no detectable hemolysis or other complications. Glucose should be added to resuscitation fluids when the blood glucose level drops below 300 mg/dL.

**Electrolytes**

The guidelines for the administration of potassium, magnesium, and phosphorus are similar to those for DKA.

**Insulin**

Low-dosage insulin, such as that administered in the patient with DKA, is generally effective and safe when the restoration of volume has been instituted.

**Other Considerations**

A vigorous search for the underlying precipitant for HHNC must be pursued. Response to therapy should be followed in the manner described for patients in DKA. Phenytoin (Dilantin) is contraindicated for the seizures of HHNC because it is often ineffective and may impair endogenous insulin release. Phenytoin-induced HHNC even occurs in nondiabetic patients. Low-dosage subcutaneous heparin may be

---

**BOX 124-9 SUMMARY OF TREATMENT FOR HYPERGLYCEMIC HYPEROSMOLAR NONKETOTIC COMA**

Identify HHNC, then treatment is the same as initial DKA treatment.

1. Supplement insulin.
   - Bolus: 0.05–0.1 U/kg regular insulin IV
   - Maintenance: 0.05–0.1 U/kg regular insulin IV
   - **Caution:** Serum glucose rapidly corrects with fluid administration alone; monitor glucose to avoid hypoglycemia.
   - Change IV solution to D$_5$W 0.45% NS when glucose $\leq$ 300 mg/dL.

2. Rehydrate.
   - Rapid administration of 2–3 L NS over first several hours
   - CVP monitoring may be necessary in patients with history of heart disease.
   - Correct one half of fluid deficit in first 8 hours, remainder over 24 hours.

3. Correct electrolyte abnormalities.
   - Sodium
     - Correct with administration of NS and 0.45% NS.
   - Potassium
     - First ensure adequate renal function.
     - Add 20–40 mEq KCl to each liter of fluid.
   - Phosphorus
     - Usually unnecessary to replenish
   - Magnesium
     - Correct with 1–2 g MgSO$_4$ (in first 2 L if magnesium is low).

4. Correct acidosis.
   - Add 44–88 mEq/L to first liter of IV fluids only if pH $\leq$ 7.0.
   - Correct to pH 7.1.

5. Search for and correct underlying precipitant.

6. Monitor progress and keep meticulous flow sheets.
   - Vital signs
     - Fluid intake and urine output
   - Serum glucose, K$^+$, Cl$^-$, HCO$_3^-$, CO$_2$, pH, ketones
   - Amount of insulin administered

7. Admit to hospital or intensive care unit.

CVP, central venous pressure; DKA, diabetic ketoacidosis; HHNC, hyperglycemic hyperosmolar nonketotic coma; NS, normal saline.
indicated to lessen the risk of thrombosis, which is increased by the volume depletion, hyperviscosity, hypotension, and inactivity associated with HHNC.

**Complications**

Reasons for high morbidity and mortality rates are not always clear, but many patients with HHNC are elders who have underlying cardiac and renal disease. Pediatric HHNC differs from adult HHNC in that children have a much higher incidence of fatal cerebral edema. Other causes for morbidity and mortality are similar to those described for DKA. The mortality rate of treated HHNC patients has been 40 to 70% in the past, but now ranges from 8 to 25%. 

**Disposition**

Patients with HHNC should be hospitalized for IV hydration, glucose control, and evaluation of precipitating and complicating conditions.

**LATE COMPLICATIONS OF DIABETES**

Late complications of diabetes cause significant morbidity and mortality. They develop approximately 15 to 20 years after the onset of overt hyperglycemia. The Diabetes Control and Complications Trial showed that tight glycemic control significantly reduces the risk of microvascular disease, such as microalbuminuria (the earliest sign of nephropathy), neuropathy, and retinopathy, but at the expense of greatly increasing the risk of recurrent hypoglycemia.

**Vascular Complications**

Diabetes is associated with an increased risk for atherosclerosis and thromboembolic complications, which are a major cause of morbidity and premature death. The cause of accelerated atherosclerosis is unknown, although it is probably related to oxidized low-density lipoprotein and increased platelet activity. Atherosclerotic lesions are widespread, causing symptoms in many organ systems. Coronary artery disease and stroke are common. Diabetic patients have an increased incidence of “silent” MI, complicated MI's, and congestive heart failure. Peripheral vascular disease is noted clinically by claudication, nonhealing ulcers, gangrene, and impotence.

**Diabetic Nephropathy**

Renal disease is a leading cause of death and disability in diabetic patients. Approximately one half of end-stage renal disease in the United States is caused by diabetic nephropathy. Diabetic nephropathy involves two pathologic patterns: diffuse and nodular. Clinical renal dysfunction does not correlate well with the histologic abnormalities. Disease usually progresses from enlarged kidneys with elevated GFR to the appearance of microalbuminuria, to macroproteinuria with hypertension, reduced GFR, and renal failure. The appearance of microalbuminuria correlates with the presence of coronary artery disease and retinopathy.

Azotemia generally does not begin until 10 to 15 years after the diagnosis of diabetes. Progression of renal disease is accelerated by hypertension. Meticulous control of diabetes can reverse microalbuminuria and may slow the progression of nephropathy. Hypertension should be aggressively managed. Angiotensin-converting enzyme inhibitors are effective in controlling hypertension and lowering microalbuminuria. Chronic hemodialysis and renal transplantation are unfortunate endpoints for many diabetic patients with renal disease.

**Retinopathy**

Diabetes is a leading cause of adult blindness in the United States. Approximately 11 to 18% of all diabetic patients have treatable diabetic retinopathy ranging from mild to severe and manifesting in many forms. The severity of diabetic retinopathy is clearly related to the quality of glycemic control.

Background (simple) retinopathy is found in most diabetic patients who have prolonged disease. Background retinopathy is characterized by microaneurysms, small vessel obstruction, cotton-wool spots or soft exudates (microinfaracts), hard exudates, and macular ischemia. The characteristics of proliferative retinopathy are vitreal hemorrhage and retinal detachment, which may ultimately cause unilateral vision loss. Treatment for diabetic retinopathy is photocoagulation.

Maculopathy is background retinopathy with macular involvement. It results primarily in a deficit of central vision. As with proliferative retinopathy, it is vital that the patient be under the care of an ophthalmologist. Laser therapy in the early stages can dramatically alter the course of this disabling disease.

The diabetic patient may present with complaints ranging from acute blurring of vision to sudden unilateral or even bilateral blindness. Less often, diabetic patients have more gradual vision loss caused by the common senile cataract or the “snowflake” cataract, which may disappear as hyperglycemia is corrected. The associated hyperlipidemia of diabetes may lighten the color of retinal vessels, producing lipidemia retinialis. Anterior ischemic optic neuropathy has been reported.

Diabetic patients with retinopathy should be referred to an ophthalmologist. Even in those with normal vision, ophthalmologic procedures may limit visual loss or prevent crises such as neovascular glaucoma.

**Neuropathy**

Both autonomic and peripheral neuropathies are well-known complications of diabetes. The prevalence of peripheral neuropathy ranges from 15 to 60%. The cause of the neuropathy is not clearly understood, but evidence suggests several factors in its development. Neuropathy may result from the effects of diabetic vascular disease on the vasa nervorum. Myoinositol, the polyol pathway, and nonenzymatic glycosylation of protein may have roles. All these factors are related to an elevated blood glucose level. Neurologic manifestations of diabetes may regress with improved glycemic control. Pathologically, segmental demyelination occurs with loss of both myelinated and unmyelinated axons, particularly those affecting the distal part of the peripheral nerve.

Several distinct types of neuropathy have been recognized in diabetes. Peripheral symmetrical neuropathy is a slowly progressive, primary sensory disorder manifesting bilaterally with anesthesia, hyperesthesia, or pain. The pain is often severe and worse at night. It affects upper and lower extremities, although lower extremities and the most distal sections of the involved nerves are most often affected. There may be a motor deficiency as well. Pain is very difficult to control. Simple pain medications, amitriptyline, and fluphenazine are effective for some patients.

Mononeuropathy, or mononeuropathy multiplex, affects both motor and sensory nerves, generally one nerve at a time.
The onset is rapid, with wasting and tenderness of the involved muscles. Clinically, sudden onset of wristdrop, footdrop, or paralysis of cranial nerves III, IV, and VI is noted. Diabetic truncal mononeuropathy occurs rapidly in a radicular distribution. In contrast to other mononeuropathies, it is primarily, if not exclusively, sensory. If it causes pain, it may mimic that of an MI or acute abdominal inflammation. Like diabetic mononeuropathy, it may be most bothersome at night and generally resolves in a few months. Whereas diabetic mononeuropathy is often the first clue of diabetes, truncal mononeuropathy is more often found in known diabetic patients.

Autonomic neuropathy occurs in many forms. Neuropathy of the GI tract is manifested by difficulty swallowing, delayed gastric emptying, constipation, or nocturnal diarrhea. Impotence and bladder dysfunction or paralysis may occur. Orthostatic hypotension, syncope, and even cardiac arrest have resulted from autonomic neuropathy. Diabetic diarrhea responds to diphenoxylate and atropine, loperamide, or clonidine. Orthostatic hypotension is treated by sleeping with the head of the bed elevated, avoidance of sudden standing or sitting, and the use of full-length elastic stockings.

The Diabetic Foot. Approximately 20% of hospitalizations in diabetic patients are related to foot problems. Sensory neuropathy, ischemia, and infection are the principal contributors to diabetic foot disease. Loss of sensation leads to pressure necrosis from poorly fitting footwear and small wounds going unnoticed. The most common cause of injury is pressure on plantar bony prominences. All neuropathic foot ulcers should be assessed for infection and débrided of devitalized tissue, and radiographs should be obtained to examine for the presence of foreign bodies, soft tissue gas, or bone abnormalities. Weightbearing must be eliminated by total-contact casting.

Not all ulcers are infected. Infection is suggested by local inflammation or crepitation. Conversely, some uninfamed ulcers are associated with underlying osteomyelitis. Most mild infections are caused by gram-positive cocci, such as *Staphylococcus aureus* or streptococci, and may be treated with oral antibiotics, a strict non-weight-bearing regimen, meticulous wound care, and daily follow-up. This approach may not be possible when patients are deemed unreliable, do not have good home support, or do not have ready access to follow-up care.

Deeper, limb-threatening infections—as evidenced by full-thickness ulceration, cellulitis greater than 2 cm in diameter with or without lymphangitis, bone or joint involvement, or systemic toxicity—are usually polymicrobial in origin and caused by aerobic gram-positive cocci, gram-negative bacilli, and anaerobes. These patients require hospitalization and, after culture, IV empirical antimicrobial therapy with ampicillin-sulbactam, ticarcillin-sulbactam, cefoxitin, imipenem, or a fluoroquinolone and clindamycin; strict non-weight-bearing status; tight glycemic control; early surgical intervention for débridement; drainage; and meticulous wound care.

Occult osteomyelitis should be considered in all cases of neuropathic ulceration. Up to one third of patients must undergo amputation.

Infections

Diabetic patients are more susceptible to complications of infections because of their inability to limit microbial invasion with effective polymorphonuclear leukocytes and lymphocytes. They have an increased incidence of extremity infections and pyelonephritis compared with the general population. In addition, they are particularly susceptible to certain other infections such as tuberculosis, mucocutaneous candidiasis, intertrigo, mucormycosis, soft tissue infections, nonclostridial gas gangrene, osteomyelitis, and malignant *Pseudomonas* otitis externa. Treatment for diabetic patients with infection includes rapid culture and antibiotics, glycemic control, and generally hospitalization.

Cutaneous Manifestations

Dermal hypersensitivity is manifested by pruritic, erythematous inductions that occur at insulin injection sites. The declining prevalence of this condition has paralleled the improved purification of insulin. Insulin lipothyrophy likewise seems to be a result of insulin impurities and is manifested as subcutaneous depressions at injection sites. Although lipoatrophy is now more common than dermal hypersensitivity, its prevalence has also declined sharply because insulin preparations have improved. Insulin lipohypertrophy is manifested by raised areas of subcutaneous fat deposits at insulin injection sites. These lesions generally reflect the failure of the patient to rotate injections sites adequately. They resolve spontaneously over months if insulin injection is avoided in the affected areas and sites are properly rotated.

Insulin pumps are often associated with localized skin problems, usually a reaction to the tape securing the tubing and needles. Occasionally, sensitivity to the catheters is seen. Skin infections at the site of injection are the most common complication of insulin pumps. Changing the patient to buffered pure-pork from unbuffered beef-pork insulin is the only intervention that seems to reduce the rate of infection. A few patients have been noted to develop hard nodules at the injection site. The cause of these nodules is uncertain.

Diabetic patients who use oral hypoglycemic agents may develop rashes associated with these medications. After consuming ethanol, approximately 30% of type 2 patients taking chlorpropamide exhibit a “flush” consisting of redness of the face and neck and a sense of warmth or burning. Patients may demonstrate urticaria in response to both insulin and oral hypoglycemics.

Diabetic skin conditions include fungal infections, acanthosis nigricans, necrobiosis lipidica diabeticorum, xanthoma diabeticorum, bullous diabeticorum, and diabetic dermopathy. *Acanthosis nigricans* is characterized by a velvety brown-black thickening of the keratin layer, most often in the flexor surfaces. It is the cutaneous marker for a group of endocrine disorders with insulin resistance. *Necrobiosis lipidica diabeticorum* begins as erythematous papular or nodular lesions, usually in the pretibial area, but in other areas as well. The early lesions may contain telangiectasias. These lesions spread and frequently form a single pigmented area of atrophic skin, often with a yellow and sometimes ulcerated center and an erythematous margin. A history of previous trauma is sometimes found.

The three forms of diabetic thick skin are (1) scleroderma-like skin changes of the fingers and dorsum of the hand associated with stiff joints and limited mobility, (2) clinically inapparent but measurable thick skin, and (3) “scleroderma adultorum,” or increased dermal thickness on the back and posterior upper neck in middle-aged, overweight patients with type 2 diabetes. *Xanthoma diabeticorum* is evidence of the hyperlipidemia associated with diabetes. It is similar to the xanthoma found in nondiabetic hyperlipidemic patients. Xanthomas have an erythematous base and a yellowish hue.

*Bullous diabeticorum* is a rare occurrence. Bullae are usually filled with a clear fluid and are most often found on the extremities, especially the feet. The fluid is occasionally
slightly hemorrhagic. The bullae usually heal spontaneously without scarring.

**Diabetic dermopathy**, or “skin spots,” is the most common finding in diabetes. It arises as discrete, depressed, and brownish lesions generally less than 15 mm in diameter and found in the pretibial area.

Resistant, aggressive *impetigo* or *intertrigo* should suggest diabetes.

### Insulin Allergy

Insulin allergy is mediated by immunoglobulin E and is manifested by local itching or pain and delayed brawny edema, urticaria, or anaphylaxis. Systemic reactions are usually seen in patients who have previously discontinued insulin and then resumed therapy. Mild reactions may be treated with antihistamines, whereas anaphylaxis must be treated with epinephrine. Patients with significant reactions must be admitted for desensitization.

### Diabetes in Pregnancy

Before the discovery of insulin in 1922, diabetes in pregnancy was associated with a fetal death rate of 60 to 72% and maternal morbidity of approximately 30%. In 1977, a linear relationship between glycemic control and perinatal mortality was discovered. Strict metabolic control is now a goal in all diabetic pregnancies.

Pregnant patients should be watched extremely closely and aggressively treated for impeding or actual DKA. For a variety of reasons, pregnant women have a special predisposition to both glucose intolerance and excess ketone production. Although uncommon, DKA may cause perinatal asphyxia and reduce fetal oxygen delivery. Intellectual deficits in offspring have been associated with maternal ketonuria from any cause.

Pregnancy is associated with progression of retinopathy for unknown reasons. Whether pregnancy worsens diabetic nephropathy or hastens the progression to end-stage renal disease is controversial. Although uncommon, DKA may cause perinatal asphyxia and reduce fetal oxygen delivery. Intellectual deficits in offspring have been associated with maternal ketonuria from any cause.

Hypoglycemia is common in pregnancy in part because of intensive insulin treatment to maintain euglycemia. Hypoglycemic unawareness is not uncommon. The effects of hypoglycemia on the fetus are unclear. Ketoacidosis is associated with a 50 to 90% fetal mortality rate.

### New-Onset Hyperglycemia

Patients often present to the ED with typical diabetic symptoms such as polyuria, polydipsia, and polyphagia. Many have serum glucose greater than 200 mg/dL but are not ketogenic. These patients with normal electrolytes may be treated with IV hydration alone or with insulin, often reducing the glucose to 150 mg/dL. In reliable patients whose initial glucose is greater than 400 mg/dL, initiation of oral hypoglycemic therapy may be appropriate, with lifestyle modification. An HbA1c value should be obtained before initiation of therapy to help evaluate treatment. Initial therapy with sulfonylureas is appropriate; glyburide (2.5–5 mg once daily) or glipizide (5 mg once daily) is recommended. In obese patients or those in whom sulfonylureas are contraindicated, metformin may be an alternative. Follow-up should be stressed and warning signs of hypoglycemia discussed.

### Oral Hypoglycemic Agents

The widespread availability of a variety of oral medications for hyperglycemia, some with serious side effects, requires the emergency physician to be familiar with these drugs. *Sulfonylureas*, developed in the 1940s, continue to be the mainstay of oral diabetes treatment. These drugs increase insulin secretion by binding to specific beta-cell receptors. This class of drugs works best in patients with early onset of type 2 diabetes and fasting glucose levels less than 300 mg/dL. This class of drugs is contraindicated in patients with a known allergy to sulfa agents. Patients with renal failure may be predisposed to hypoglycemia. *Metformin* is an agent in the biguanide class. It works by decreasing hepatic glucose output and increasing peripheral uptake of glucose, leading to decreased insulin resistance and lower blood glucose. Used alone, metformin does not cause hypoglycemia, but it is contraindicated in patients with renal insufficiency and metabolic acidosis. Metformin is renally excreted. Metformin should be withheld for 48 hours before or after administration of iodinated contrast media because of the risk of acidosis from transient decrease in renal function. Metformin must be used with caution in patients with hypoxemia, liver compromise, and alcohol abuse. These patients are at increased risk for developing lactic acidosis, which has a 50% mortality rate.

The *thiazolidinediones* reduce insulin resistance and are especially useful in patients who require large amounts of insulin and still lack adequate glucose control. Because of hepatotoxicity, troglitazone has been removed from the market. Pioglitazone and rosiglitazone are approved for monotherapy. Liver function should be monitored for at least 1 year after the initiation of therapy with thiazolidinediones. 

*α*-Glucosidase inhibitors delay intestinal monosaccharide absorption and prevent complex carbohydrate breakdown. They must be titrated to minimize GI side effects and should not be used in patients with certain GI disorders. Liver function monitoring is required because of dose-dependent hepatotoxicity.

*Reposuglinide* is similar to the sulfonylureas in action and mechanism. It has a more rapid onset of action, involves less risk of hypoglycemia, and is suitable for patients allergic to sulfa. Care should be used in patients with renal or hepatic dysfunction.

*Exanatide* is a GLP (glucagon-like peptide) agonist. GLP stimulates release of insulin from pancreatic cells. GLP itself has a half-life of only a few minutes, but the GLP agonists bind to the GLP receptor on the pancreas and have a much longer half-life.

*Vildagliptin* and *sitagliptin* are classified as DPP-4 (dipeptidyl peptidase-4) inhibitors. DPP-4 degrades endogenous GLP; the DPP-4 inhibitors, by preventing this degradation, prolong the half-life of GLP and increases insulin secretion.

### New Trends

Changes in the therapy of diabetes include greater use of human insulin, which has prevented some of the adverse reactions to beef and pork products. Unfortunately, some patients demonstrate sensitivity reactions even to subcutaneously
injected human insulin. More physicians are teaching their type 1 patients and families how to administer glucagon to treat severe hypoglycemia. Initiation of immunosuppressive therapy at the initial diagnosis of type 1 diabetes can prolong the patient′s ability to secrete insulin. However, this beneficial effect, whether achieved by azathioprine or cyclosporine, is not usually sustainable. The potential side effects of immunosuppressive agents have precluded large trials in patients early in their disease. Prophylactic insulin therapy, nicotinamide, oral insulin, or glutamate decarboxylase and avoidance of cow′s milk may prevent or delay the onset of type 1 diabetes in patients at risk.

Glycemic control now involves improved technology and more widespread individual monitoring. More patients alter their insulin dosages daily in response to their findings. Diabetic patients with tight glycemic control benefit by limiting the progression of microvascular disease: neuropathy, renal disease, and certain types of retinopathy. However, they are more likely than other diabetic patients to experience hypoglycemic episodes.

Emergency physicians and out-of-hospital care providers are encountering patients with insulin pumps. Many insulin pumps are available, each having a pump mechanism, a reservoir for insulin, tubing, and indwelling subcutaneous needles. They are attached, usually with tapes, to the patient′s body and administer insulin at a regular adjustable rate. Most pumps also allow the patient to administer additional boluses of insulin as necessary. These pumps support tight glycemic control and are acceptable to some patients. However, motivated patients can achieve equivalent control by adjusting daily injections. Insulin pumps are associated with a variety of complications (e.g., iatrogenic hypoglycemia).

Because glucose rotates the polarization of light waves, new fiberoptic technology has been developed to determine blood glucose noninvasively. This technology may be applied to the insulin pumps in the future.

Inhaled insulins have been studied, and one was even marketed briefly; further research into this area is likely. A variety of available insulins, including ultra-short-acting (Humalog) and long acting (Lantus) have come out in recent years, which have provided a wider array of possibilities in diabetes management.

The basic concepts of the diabetic diet remain unchanged, although many studies emphasize foods and medications that alter glucose absorption. Various high-fiber diets have improved glycemic control. The mostly beneficial but occasionally deleterious effects of exercise have also been elaborated.

Newer therapies include pancreatic and pancreatic beta-cell transplants. Solid-organ pancreatic transplantation remains controversial among both diabetologists and transplant surgeons. Transplantation ameliorates many secondary complications of diabetes, such as nephropathy, neuropathy, gastroparesis, retinopathy, and microvascular changes. The percentage of grafts functioning after 1 year and the 1-year survival rate of patients are greater than 75% in selected medical centers. Rejection, post-transplantation pancreatitis, and graft thrombosis, as well as other vascular and immunosuppression problems, continue to plague transplant recipients.

**Pramlintide** is part of a new class of drugs called amylin analogues. These decrease gastric emptying and decrease glucagon secretion. Currently, pramlintide must be administered by subcutaneous injection after a meal.

Other new areas for research have included agents that increase urinary excretion of glucose or increase hepatic gluconeogenesis.

### Key Concepts

- Hypoglycemia may be associated with significant morbidity and mortality. When the diagnosis is suggested and, if possible, confirmed by laboratory evaluation, treatment should be initiated immediately.
- Hypoglycemia caused by oral hypoglycemic agents may be prolonged. Patients should be observed for an extended period or hospitalized.
- The essential treatment of DKA includes restoration of insulin, correction of dehydration, correction of potassium level, correction of acidosis, and treatment of the underlying cause.
- Hyperglycemic hyperosmolar nonketotic coma is often associated with focal neurologic signs that resolve with treatment. The essentials of treatment are correction of profound dehydration, correction of electrolytes, and treatment of the underlying cause.

PERSPECTIVE

Rhabdomyolysis, defined as the dissolution or disintegration of striated muscle, describes a clinical and biochemical syndrome resulting from the release of intracellular contents into the extracellular fluid and circulation. The diagnosis of rhabdomyolysis rests on measurement of these released substances in either plasma or urine. The classic presentation includes symptoms of myalgias, weakness, red to brown urine due to myoglobinuria, and elevated serum muscle enzymes, such as creatine kinase (CK). Approximately 26,000 incident cases of rhabdomyolysis are reported annually. The spectrum of disease severity ranges from an asymptomatic elevation of muscle enzymes to life-threatening electrolyte imbalances, acute renal failure, multiorgan failure syndrome, and death.

Historically, the earliest reference to rhabdomyolysis occurs in the Old Testament, from the Book of Numbers. During the Exodus, the Israelites consumed large amounts of quail, which fed on hemlock seeds, and many became ill and died from an illness described by intense muscle pain and weakness. In the late 19th century a clinical syndrome of muscle pain, weakness, and brown urine was called “Meyer-Betz disease” in the German literature. In 1941, Bywaters and Beall described the clinical course of four victims with crush injuries to the limbs after air raids during World War II. They noted the link between muscle injury and renal dysfunction in their classic monograph, as follows:

“The patient has been buried for several hours with pressure on a limb. On admission he looks in good condition except for swelling of the limb, some local anesthesia and whealing. The hemoglobin, however, is raised and a few hours later despite vasoconstriction made manifest by pallor, coldness and sweating, the blood pressure falls. This is restored to the pre-shock level by (often multiple) transfusions of serum, plasma, or occasionally, blood. Anxiety may now arise concerning the circulation in the injured limb, which may show diminution of arterial pulsation distally, accompanied by all the changes of incipient gangrene. Signs of renal damage soon appear and progress, even though the crushed limb be amputated. The urinary output, initially small, owing perhaps to the severity of the shock, diminishes further. The urine contains albumin and many dark brown or black granular casts, which later decrease in number. The patient is alternately drowsy and anxiously aware of the severity of his illness. Slight generalized edema, thirst, and incessant vomiting develop, and the blood pressure often remains slightly raised. The blood urea and potassium, raised at an early stage, become progressively higher, and death occurs comparatively suddenly, frequently within a week. Necropsy reveals necrosis of muscle and in the renal tubules, degenerative changes and casts containing brown pigment.”

Acute renal failure (ARF) is one of the most serious complications of rhabdomyolysis, and the presence of ARF is associated with multisystem organ failure and a higher mortality rate. Well-designed prospective studies of rhabdomyolysis and its complications are lacking, so the true incidence of ARF in this setting is unknown but is estimated at 4 to 33%. Approximately 5 to 15% of patients hospitalized with ARF in the United States have rhabdomyolysis as the cause.

PRINCIPLES OF DISEASE

Anatomy and Physiology

Skeletal muscle is the largest organ in the human body. The functioning of muscle cells is critically dependent on a healthy cell membrane, the sarcolemma, which maintains ionic gradients and ensures proper metabolic functioning. The sarcolemma contains sodium-potassium pumps, calcium protein-carrier pumps, and other channels and structures. The sodium-potassium pump moves sodium out and potassium into the sarcoplasm. More sodium is transported out than potassium is transported in, creating a net negative intracellular charge. A sodium concentration gradient is thus created. Normally, the concentration of intracellular sodium ions is very low, approximately 10 mEq/L, when compared with the extracellular fluid.

Also found within a cell’s sarcoplasm, myoglobin is the major heme protein supplying oxygen to skeletal and cardiac muscle.
Myoglobin has a higher affinity than hemoglobin for oxygen and thus facilitates an influx of oxygen into muscle cells. Under normal circumstances, plasma myoglobin is bound to haptoglobin and the concentration is low. However, if greater than 100 g of skeletal muscle is damaged, serum haptoglobin-binding capacity is exceeded, and “free” myoglobin is filtered by the glomerulus, producing the classic dark-colored urine of rhabdomyolysis. When myoglobin precipitates in the glomerular filtrate, it causes renal tubular obstruction and ARF.

Skeletal muscle cytoplasm contains proteases and other proteolytic enzymes, which decompose myofibrillar proteins for recycling. The activity level of these enzymes depends on intracellular calcium levels. In the cell’s normal physiologic state, these enzymes have low activity; however, with significant elevations of intracellular calcium, these proteolytic enzymes are maximally disinhibited and become destructive to the cell.

**Pathophysiology**

Despite the large number of diverse diseases leading to rhabdomyolysis, the final common pathway of injury involves damage to the sarcolemma, resulting in a rise in the intracellular calcium and the liberation of intracellular contents, such as myoglobin, aldolase, aspartate transaminase, lactate dehydrogenase, CK, potassium, uric acid, and phosphorus. Excess intracellular calcium causes a pathologic interaction between myosin and actin, and activates intracellular proteases, phospholipases, and other proteolytic enzymes, resulting in further cell damage and destruction.

Direct cellular membrane damage (e.g., crush injury) or ATP depletion results in loss of the ionic gradients created by the sodium-potassium pumps and the sodium-calcium channels. Membrane damage from direct trauma makes the sarcolemma more permeable to calcium, which follows the electrochemical gradient and travels into the cell. This causes extracellular hypocalcemia and intracellular hypercalcemia. In atraumatic rhabdomyolysis, lack of adequate ATP causes membrane ion pump dysfunction, which also results in excess intracellular calcium accumulation. ATP depletion may result from a mismatch between energy supply and demand (e.g., vigorous or prolonged exercise) or a defect in energy use (e.g., McArdle’s syndrome or absence of muscle phosphorylase).

Once destruction of the myocyte begins, myoglobin is released. As the levels of free plasma myoglobin increase, excess myoglobin is filtered by the kidneys and enters the urine. Excess myoglobin, when coupled with hypovolemia and acidosis, can precipitate and block renal tubular flow. Although universally present, tubular obstruction may not be the primary event in the development of acute intrinsic renal failure (AIRF) associated with rhabdomyolysis. Interestingly, myoglobin infusions in normovolemic rabbits with a urine pH above 6 have no deleterious effect on kidney function. Other studies have demonstrated that myoglobin dissociates into its two components—globin and ferrihemate—at pH values of 5.6 or less. Since infusions of the globin component have no effect on renal function even in the presence of hypovolemia and acidic urine, ferrihemate may be the toxic subunit of myoglobin. Myoglobin may also be directly toxic to the renal tubular cells. The most common cause of rhabdomyolysis-induced ARF is AIRF, which is defined as a decrease in the glomerular filtration rate caused by a toxic or ischemic event that is not reversed on discontinuation of the insult. AIRF is invariably associated with some degree of tubular injury and has a characteristic urine profile of low specific gravity (\( < 1.010 \)), brown casts, and a fractional excretion of sodium greater than 1% (Box 125-1).

**Compartment syndrome may be a cause or a complication of rhabdomyolysis.** A compartment syndrome exists when the circulation to tissues within a closed space is compromised by increased pressure within that space. The excessive pressure may occur as a result of a decrease in the size of the compartment, an increase in the size of the contents of the compartment, or a combination of both. Once established, compartment syndrome tends to be self-sustaining because (1) capillaries become occluded as a result of the increased pressure; (2) venous pressure increases, further decreasing perfusion pressure; and (3) arteriolar vasospasm leads to tissue ischemia, swelling, and edema. The swelling and edema cause an increase in the compartmental pressure and the cycle continues. In 2 to 4 hours, ischemic skeletal muscle may develop functional deficits, which may become irreversible after 10 hours. Within 30 minutes of ischemia, nerve tissue exhibits reversible deficits that may become permanent after 12 to 24 hours of ischemia.
Etiology

The relationship between traumatic muscle injury and kidney failure has been reviewed extensively over the past 60 years. In the mid-1970s the first references were made to nontraumatic rhabdomyolysis. Since then, the number of known causes for this syndrome has greatly increased. In addition to trauma and compression, exercise, alcohol, drugs, infections, and seizures are the leading causes of rhabdomyolysis. In many cases, the etiology is multifactorial (Box 125-2).

Metabolic Myopathies

Certain genetic defects do not allow appropriate use of carbohydrates or lipids as energy substrates, resulting in ATP depletion. These disorders include defects in glycolysis or glycogenolysis, defects of fatty acid oxidation, and dysfunction of cellular mitochondria. Each entity can cause recurrent attacks of reversible rhabdomyolysis or progressive weakness. These enzyme defects are found in 23 to 47% of adult patients with rhabdomyolysis. A genetic defect should be considered, particularly in a child who has no other apparent risk factors but has recurrent episodes of rhabdomyolysis, exercise intolerance, and muscle cramps. A genetic myopathy may be confirmed by a muscle biopsy.

Trauma and Compression

Most information regarding rhabdomyolysis from trauma and compression has been obtained from mass-casualty incidents such as traffic accidents and building collapses following earthquakes. In fact, crush-induced rhabdomyolysis is the most frequent cause of death after earthquakes, apart from trauma. Thus, rhabdomyolysis should be expected in victims of crush injury. Direct mechanical injury to the sarcolemma disrupts its homeostatic functions. Sodium and calcium travel down their concentration gradients into the intracellular fluid, resulting in an abrupt rise in the intracellular calcium and an influx of water. The elevated calcium then activates enzymes destructive to the cell and sarcolemma, and the water influx contributes to intravascular volume depletion.

In addition to overt trauma, immobilization in one position due to coma or altered mental status may lead to compression-induced traumatic rhabdomyolysis. It can be seen in surgical patients due to improper operative positioning (e.g., lithotomy) during a long procedure, as well. Recently, there has been a rise in documented cases of rhabdomyolysis following bariatric surgery. Identified risk factors include prolonged surgery (>4 hours), presence of diabetes, and body mass index (BMI) greater than 40.

Exertion

Rhabdomyolysis can result from prolonged or strenuous exercise and is seen in both trained and untrained athletes. Eccentric exercise (work done by a muscle during lengthening) is more damaging to muscle fibers, as evidenced by higher CK levels, than concentric exercise (work done by a muscle during shortening). Hot conditions contribute to the incidence of exertional rhabdomyolysis because of increased dehydration and increased activity of heat-sensitive degradative enzymes. Hypokalemia increases the risk of exertional rhabdomyolysis, since hypokalemia limits vasodilation and perfusion of the muscle microvasculature. With prolonged exercise, the sarcolemmic ion pumps may also fail because of a depletion of cellular energy sources, specifically ATP. The failure of these pumps leads to elevated intracellular calcium and subsequently rhabdomyolysis, which, coupled with dehydration and acidosis from lactic acid production, can cause ARF. Exertional rhabdomyolysis is not always the result of voluntary muscle exertion, since the same pathophysiology is seen in patients with status epilepticus, myoclonus, dystonia, chorea, tetanus, psychotic agitation, and mania.

Electrical Current

Rhabdomyolysis occurs in approximately 10% of patients who initially survive a high-voltage electrical injury or lightning strike. Note that the severity of rhabdomyolysis is not related to the size of the wound or the site of entry. Rhabdomyolysis from electrical current appears to be a result of both the heat generated by the electrical current and the direct effects of the current on the sarcolemma (electroporation).

Heat and Cold Injury

Multiple disorders can raise the core body temperature and result in sarcolemma disruption. Neuroleptic malignant syndrome (fever in patients treated with phenothiazines or haloperidol), malignant hyperthermia (rapid rise in body temperature after anesthesia with halogenated hydrocarbons or succinylcholine), and both classic and exertional heatstroke are some of the most common causes. In hyperpyrexic syndromes, cellular energy demands outstrip available energy supplies, causing membrane dysfunction and cellular injury.

Hypothermia may also cause rhabdomyolysis, most likely through cold-induced ischemia and direct injury to components of the sarcolemma, which cannot maintain structural integrity below certain temperature levels.

Drugs and Toxins

Drugs in almost every class of medication have been implicated as a cause of rhabdomyolysis. Common offenders include ethanol, cocaine and other licit and illicit drugs, lipid-lowering agents, carbon monoxide, and biologic toxins.

Ethanol. Ethanol is directly toxic to the skeletal muscle cell membrane, and this toxicity appears to be potentiated by starvation. For this reason, ethanol-induced rhabdomyolysis is often seen in patients who are “binge drinkers.” Electrolyte abnormalities also play a role, since chronic alcohol abusers often have hypokalemia, hypophosphatemia, and hypomagnesemia. These deficiencies, coupled with ethanol’s direct sarcolemmic toxic effects, make the ethanol abuser more susceptible to rhabdomyolysis.

Ethanol is also a sedative-hypnotic, which can induce obtundation and lead to immobilization of a body part with...
external compression of its blood supply. In addition, excessive motor activity from seizures or delirium tremens can induce rhabdomyolysis.

**Cocaine.** The incidence of rhabdomyolysis in patients who use cocaine varies from 5 to 30% in published reports. Cocaine may produce rhabdomyolysis by several mechanisms; hypotheses include cocaine-induced vasospasm with resultant muscle ischemia, excessive energy demands placed on the sarcoplasmic reticulum, and direct toxic effects on myocytes. Seizures, agitation, trauma, and hyperpyrexia may also play a role. In general, the severity of rhabdomyolysis parallels the severity of intoxication. Intravenous cocaine may be associated with a higher incidence of rhabdomyolysis-induced ARF than for smoking cocaine.

**Other Illicit Drugs.** Agents such as d-lysergic acid diethylamide (LSD); phencyclidine hydrochloride (PCP); sympathomimetics, such as amphetamines; and “ecstasy” (MDMA; 3,4-methylenedioxymethamphetamine) may also cause rhabdomyolysis. Delirium and agitation, resulting in involuntary and voluntary muscle contraction, may raise energy demands of muscle cells. The increased demand may outstrip the supply of normally available ATP.

**Lipid-Lowering Agents and Other Licit Drugs.** The 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor lipid-lowering agents (e.g., lovastatin, simvastatin) have been associated with rhabdomyolysis, as have the branched-chain fatty esters that inhibit liver triglyceride synthesis (e.g., Clofibrate, gemfibrozil). The mechanism of action is unclear, although statins are considered to be direct myotoxins that may interfere with ATP production through the electron transport chain. Statins may cause rhabdomyolysis when used alone or with other drugs, particularly gemfibrozil. Patients with preexisting renal dysfunction, hypothyroidism, and inflammatory myopathies may be at greater risk. Other direct myotoxins include colchicine and immunosuppressants such as cyclosporine. Overuse of diuretics or cathartics, leading to severe hypokalemia and dehydration, may also result in rhabdomyolysis.

**Carbon Monoxide.** Rhabdomyolysis is a known complication of carbon monoxide poisoning. The pathophysiology is unknown, but hypoxia, muscle compression from coma, and direct muscle toxic effects may play a role.

**Biologic Toxins.** Some snake envenomations cause rhabdomyolysis through direct myocyte injury resulting in the release of intracellular contents to the extracellular circulation. Species known to do this include the European additive, Australian tiger snake, Australian king brown snake, sea snakes, North and South American rattlesnakes, and the death additive. Multiple myotoxins may be present in a single venom. Stings from Africanized bees (“killer bees”) and honeybees can also cause rhabdomyolysis. This is also mediated through direct myotoxicity. Mushroom poisoning has also been associated with rhabdomyolysis.

**Infections**

Bacterial, viral, and parasitic infections have been associated with rhabdomyolysis. Many viruses have been implicated, including influenza, coxsackievirus, parainfluenza, adenovirus, herpes simplex, Epstein-Barr, cytomegalovirus, and human immunodeficiency virus (HIV). Patients classically report a history of a viral illness 1 to 2 weeks prior to the onset of myalgias and myoglobinuria. Influenza viruses A and B are the most frequently cited viral causes. Although viruses may be directly toxic to myocytes, this has not been proven. Whereas rhabdomyolysis has been reported in many patients with HIV, the independent role of this virus is unclear because many of the patients in these studies were taking multiple medications or had concurrent infections.

Bacterial infections may cause muscle damage through multiple mechanisms, including direct muscle infection in pyomyositis, as well as the release of exotoxins and cytokines, and the induction of fevers and rigors. *Legionella* is the most common known bacterial cause of rhabdomyolysis. Its myotoxic effects are mediated through an endotoxin. *Salmonella* and *Streptococcus* also can induce rhabdomyolysis through both direct myocyte invasion and inhibition of glycolytic enzymes.

Of parasitic infections, falciparum malaria (*Plasmodium falciparum*) is the most notorious for causing rhabdomyolysis, as patients have high fevers, rigors, vomiting, and ARF.

**Electrolyte Abnormalities**

A variety of electrolyte disorders, particularly hypophosphatemia and hypokalemia, have been associated with rhabdomyolysis. Hypophosphatemia is believed to cause membrane injury by severe depletion of ATP, and most cases have been described in alcoholic patients or those receiving treatment for diabetic ketoacidosis. Since potassium is a vasodilator of the microcirculation for metabolically active muscle cells, hypokalemia may prevent local vasodilation and lead to focal muscle ischemia. Hypocalcemia has also been associated with rhabdomyolysis in the setting of hypoparathyroidism. Both hyponatremia and hypernatremia have also been associated with rhabdomyolysis, with case reports of the former primarily involving hyponatremia induced by psychogenic polydipsia.

**Hypoxia and Ischemia**

Intrinsic vascular injury or obstruction, hypotension, and external compression of the blood supply to a muscle group may all cause tissue hypoxia and rhabdomyolysis. For example, it may follow orthopedic or vascular reconstruction procedures in which a tourniquet is used. When circulation is reestablished, the damaged cell is reperfused and the extruded intracellular contents, including myoglobin, are brought into the general circulation. Reperrfusion is associated with an influx of neutrophils, which release proteolytic enzymes that can directly occlude the microcirculation and cause further muscle ischemia. Certain blood disorders (e.g., sickle cell anemia) may cause vascular thrombosis, resulting in tissue hypoxia and subsequent muscle injury, as well.

**Miscellaneous Causes**

Endocrine disorders, such as diabetic ketoacidosis and nonketotic hyperglycemia, have been associated with rhabdomyolysis, possibly due to hypophosphatemia and hypokalemia and the hyperosmolar state. Rhabdomyolysis has also been frequently described in association with hypothyroidism, hyperthyroidism, and pheochromocytoma. Case reports have also been documented in the literature of rhabdomyolysis occurring in patients with inflammatory myopathies, such as dermatomyositis and polymyositis.

## CLINICAL FEATURES

Patients with rhabdomyolysis classically present with the complaints of muscle weakness, pain, and tea-colored urine. The myalgias may be focal or diffuse, depending on the underlying cause of the disease. However, a high clinical suspicion for rhabdomyolysis must be maintained in patients at risk, because
up to 50% of those with serologically proven rhabdomyolysis do not complain of myalgias or muscle weakness. In fact, in the United States, rhabdomyolysis is most often due to prolonged muscle compression in the intoxicated patient who lays motionless or in the elderly patient with dementia following a fall.

History

The history can be extremely helpful in making the diagnosis. The history should include any recent trauma or compression, excessive exertion, envenomations, infections, electrical shock, or temperature extremes. Other areas of interest are the use of prescription medications, over-the-counter drugs, alcohol or illicit drugs, known medical conditions, and a family history of muscle dysfunction or disease. Unfortunately, many patients with rhabdomyolysis are unable to provide an adequate history because of an altered sensorium.

Physical Examination

Physical examination may reveal weakness with tenderness to palpation of the affected muscle groups. Skin may be discolored, and there may be evidence of pressure necrosis. With trauma or compression, the affected area may have sensory and motor deficits that do not follow a single nerve distribution.

Some patients with severe rhabdomyolysis show bradypnea, presumably caused by diaphragmatic muscle involvement. Patients may also appear clinically dehydrated from the reduced extracellular fluid volume. Compartment syndrome is a relatively common complication of rhabdomyolysis, and thus, the exam may reveal firm muscle compartments, pain with passive extension, or neurovascular compromise of the affected extremity. Characteristic physical signs are present in only 4 to 15% of patients, however. Therefore the absence of these exam findings does not rule out the diagnosis.

DIAGNOSTIC STRATEGIES

Myoglobin

In the past, the diagnosis of rhabdomyolysis rested on the demonstration of myoglobin in the serum. Serum myoglobin, however, is an insensitive marker for rhabdomyolysis. The half-life of myoglobin in plasma is 1 to 3 hours and can be cleared completely from plasma within 6 hours after injury. Similarly, urine myoglobin, which is rapidly excreted, may also be an inaccurate measure. Myoglobinuria may be absent in patients who present late in the course of their illness, and the amount of myoglobinuria depends on the plasma concentration of myoglobin, renal function, the glomerular filtration rate, the extent of myoglobin binding in plasma, and urine flow rate.

Methods used to measure urine myoglobin include immunoassay, radioimmunoassay, and specific dipstick tests. The dipstick tests involve use of reagents (e.g., guaiac, or o-toluidine) and are only slightly less sensitive than radioimmunoassay, which is the best method available. Urinalysis typically shows brown urine with a large amount of blood on dipstick evaluation but few, if any, red blood cells (RBCs) on microscopic evaluation. This occurs because most dipstick tests cannot distinguish myoglobin from hematuria or hemoglobinuria. Protein, brown casts, and renal tubular epithelial cells may also be found.

Creatine Kinase

Measurement of CK levels (formerly CPK, creatine/creatinine phosphokinase) is a more sensitive method than myoglobin testing. CK is an excellent marker for rhabdomyolysis because it is easily measured, is present in the serum immediately after muscle injury, and is not rapidly cleared from serum (half-life is 1.5 days). In general, peak CK levels occur within 24 to 36 hours of muscle injury and diminish approximately 39% per day (Fig. 125-2). Failure of levels to decrease in this manner suggests ongoing muscle injury, possibly from an undetected compartment syndrome.

Rhabdomyolysis is not defined by a specific CK level. In general, however, in the absence of cerebral or myocardial infarction, a CK above 5000 indicates serious muscle injury, and a CK level greater than five times normal is thought to be diagnostic, although levels as high as several hundred thousand have been reported. Higher CK levels, especially levels greater than 16,000, are correlated with the development of ARF. However, since patients may have significant morbidity with only moderately elevated CK levels, even modest elevations of CK must be taken seriously. The CK subtype present in skeletal muscle is MM, but when considerable skeletal muscle injury occurs, a small amount of CK-MB is also released. The CK-MB fraction rarely exceeds 3 to 5% and is indicative of the CK-MB released from skeletal muscle rather than from concomitant myocardial damage.

Other Tests

Other laboratory evaluation may show hyperkalemia, hyperphosphatemia, hypocalcemia, hyperuricemia, and hyperalbuminemia. An elevated anion gap is characteristically present. Hyperkalemia (>5.5 mEq/L) has been reported on initial laboratory studies in 20 to 40% of patients. It is caused by a combination of intracellular potassium release from muscle necrosis and decreased renal excretion. Hyperphosphatemia results from a leakage of phosphorus from injured muscle. Levels usually do not exceed 7 mg/dL, but a normal serum phosphate level in the setting of significant rhabdomyolysis raises the possibility that hypophosphatemia was the underlying cause of the rhabdomyolysis. The most common electrolyte abnormality—hypocalcemia—occurs early, and it can be exacerbated by hyperphosphatemia. Hypercalcemia results from the deposition of calcium into damaged muscle and decreased bone responsiveness to parathyroid hormone. In one series of 76 patients, hypocalcemia was present in 63%. Hypercalcemia often develops later. Although the exact cause of hypercalcemia is unknown, it is hypothesized that calcium is mobilized from damaged muscle, and parathyroid hormone
and 1,25-dihydroxycholecalciferol levels are increased during the recovery period. The combination of elevated serum phosphate and calcium may result in precipitation of calcium phosphate in soft tissue, blood vessels, and eyes. Hyperuricemia results from the release of purines from damaged muscles. Hyperuricemia is more likely to occur in well-trained athletes with exertional rhabdomyolysis due to their increased muscle mass. Hypoalbuminemia may result from leakage of protein from injured vessels coupled with prot einuria.

Many patients with acute rhabdomyolysis demonstrate evidence of disseminated intravascular coagulopathy as a late complication. Thrombocytopenia, hypofibrinogenemia, and an elevated D-dimer with prolongation of prothrombin time may be seen. The coagulopathy is a result of muscle necrosis and liberation of activating substances (e.g., thromboplastin) from injured cells.

Some patients may have elevated levels of aspartate transaminase, alanine transaminase, and lactate dehydrogenase due primarily to muscle necrosis and less to hepatic injury from proteases released from injured muscle.

**DIFFERENTIAL CONSIDERATIONS**

Pigmenturia has a variety of causes (Box 125-3). Hematuria can be distinguished from myoglobinuria through microscopic identification of RBCs in the urine with hematuria. Note that hematuria can be present with rhabdomyolysis if there is concomitant renal trauma. Similar to myoglobinuria, hemoglobinuria demonstrates a positive dipstick test for blood but no, or few, RBCs on microscopic analysis. With hemoglobinuria, however, the plasma appears discolored as brown or red. Pigmenturia can be associated with acute intermittent porphyria, as well, although these patients generally have a very different clinical presentation, and their urine contains porphobilinogen. Bilirubin, a degradation product of heme, also causes pigmenturia when present in the urine. In this case, the urine tests positive for urobilinogen. Pigmenturia may also be a direct effect from certain drugs or foods, though the urine should test negative for blood, and the microscopic evaluation should demonstrate no RBCs.

In crush injury, the motor weakness and possible paralysis may mimic spinal injury. All trauma patients must be treated with spinal precautions, and laboratory-proven rhabdomyolysis does not rule out concurrent spinal injury. With rhabdomyolysis, however, motor function often improves as the disease is treated.

**COMPLICATIONS**

Complications of rhabdomyolysis may be categorized as early, if they occur within the first 24 hours after injury. Such early complications of rhabdomyolysis include electrolyte abnormalities, such as hyperkalemia, hypocalcemia or hypercalcemia, hyperphosphatemia, and hyperuricemia. The hyperkalemia may lead to cardiac arrhythmia and death. Hepatic dysfunction, another early complication, manifests as elevation in liver enzymes and occurs in 25% of patients. Proteases released from injured muscle are implicated in the hepatic inflammation. Renal failure and disseminated intravascular coagulopathy are later complications, more commonly developing after 24 to 48 hours. In contrast, compartment syndrome, usually developing in muscles whose expansion is restricted by tight fascia, such as the tibialis anterior, may be an early or late complication of fluid resuscitation with worsening edema.

**MANAGEMENT**

After initial stabilization and resuscitation, the primary objective in managing rhabdomyolysis should be to identify and treat the underlying cause and to mitigate the associated complications: electrolyte derangements, renal failure, coagulopathy, and compartment syndrome.

**Saline Infusion**

The mainstay of therapy for rhabdomyolysis is the administration of large volumes of saline very early in the course of the disease. Fluid is sequestered in necrotic muscle and contributes to intravascular hypovolemia and prerenal renal failure. In patients with trauma or compression, saline resuscitation should begin in the field. Delays in initiating rehydration increase the risk of oliguric and anuric renal failure. In one study, no patients who underwent aggressive saline rehydration within the first 6 hours of admission developed ARF.

Initial resuscitation should be undertaken with normal saline. Potassium-containing fluids should be avoided due to the risk of rhabdomyolysis-associated hyperkalemia. High-volume infusions should be started as soon as possible and infusion rates titrated for a urine output of 200 to 300 mL/hr. Patients may require up to 20 L of fluid in the first 24 hours to achieve adequate urine flow rates. Ideally, the amount of fluid to be administered should be determined on the basis of the clinical course or central venous pressure measurements.

**Mannitol**

Mannitol use is somewhat controversial in the treatment of rhabdomyolysis, since its use is mostly supported by animal studies and retrospective clinical studies. In one study, mannitol did not confer any benefit compared with normal saline alone. Mannitol is an osmotic diuretic, an intravascular volume expander, a renal vasodilator, and possibly a free radical scavenger. As a diuretic, mannitol increases urine flow, which may help prevent obstruction from myoglobin casts. Renal vasodilation increases renal blood flow and GFR, and...
may also decrease tubular obstruction. As a volume expander, mannitol draws fluid from the interstitial space, decreasing intravascular dehydration and potentially reducing muscular swelling. In cases of early ARF, mannitol may convert oliguric renal failure to nonoliguric renal failure, which has a somewhat better prognosis. Since mannitol is a diuretic, however, adequate volume resuscitation and urine flow should be established prior to its administration. Loop diuretics (e.g., furosemide) can acidify the urine and should not be used.18

**Urine Alkalization**

Myoglobin precipitation is enhanced in acidic conditions, and myoglobin alone may not be nephrotoxic unless accompanied by intravascular volume depletion and acidosis.20 Thus, urine alkalization theoretically facilitates renal myoglobin clearance by increasing its solubility. The goal is to keep the urine pH greater than 6.5, which can be accomplished by adding bicarbonate to intravenous fluids. Two ampules of bicarbonate in 1 L of half normal saline produce a slightly hypertonic solution. Thus, it may be prudent to add 1.5 ampules of bicarbonate to 1 L of half normal saline (or 2 ampules of bicarbonate in 5% dextrose in water, especially when mannitol, a hyperosmolar agent, is also administered. Potential adverse effects of sodium bicarbonate therapy include hypernatremia, aggravation of fluid overload in patients with congestive heart failure, and the exacerbation of hypocalcemia.

Similar to mannitol administration, alkalization as a therapeutic modality for rhabdomyolysis is being questioned, since randomized studies have demonstrated a benefit. In fact, Hosni and colleagues found no benefit of bicarbonate therapy over vigorous fluid hydration. More recently, Brown and associates reviewed the case records of 1771 critically ill trauma patients with increased CK levels and demonstrated no difference in the incidence of renal failure (22% vs. 18%), dialysis (7% vs. 6%), or mortality (15% vs. 18%) between the group that received mannitol and bicarbonate versus the group that only received saline hydration.110 Thus, further studies are needed to demonstrate if any treatment regimen is truly superior to early, vigorous saline hydration.111

**Experimental Therapies**

A potential role for iron chelators, such as desferrioxamine, is under investigation. Chelation therapy reduces renal injury in animal models.112 The theory is that iron chelation diminishes exposure to free iron, thereby decreasing lipid peroxidation and myocyte breakdown.

One case report demonstrated that hyperbaric oxygen was beneficial when used as adjunctive therapy for a patient with compartment syndrome, rhabdomyolysis, and ARF after a heroin overdose.113 Other experimental models demonstrate a reduction in muscle necrosis due to ischemia-reperfusion injury with the administration of free-radical scavengers and antioxidants, such as vitamin E and vitamin C, and minerals, such as zinc, manganese, and selenium. These, therefore, are potential therapeutic agents in the management of rhabdomyolysis.114

**General Measures**

**Electrolyte Abnormalities**

Hyperkalemia is a potentially life-threatening complication of rhabdomyolysis and must be treated. However, intravenous calcium may be ineffective as a treatment for hyperkalemia if given to a patient with hyperphosphatemia, since the calcium and phosphate may precipitate. Moreover, correction of initial hypocalcemia with intravenous calcium can exacerbate the normal hypercalcemia that occurs in the recovery phase of rhabdomyolysis when calcium deposited in the injured muscle cells is mobilized back into the extracellular space. Thus, the use of calcium for asymptomatic hypocalcemic patients should be avoided because it may raise intracellular calcium levels, promoting further muscle injury. In addition to administering potassium resin binders, as well as insulin, glucose, and bicarbonate, dialysis may be required to treat hyperkalemia. Symptomatic hypercalcemia generally requires only volume expansion and diuretic therapy. For patients with a rising or elevated potassium level, persistent acidosis, uremia, or oliguric or anuric renal failure with fluid overload, dialysis may be necessary.13,13 Dialysis with supportive care should effectively limit the morbidity and mortality from ARF associated with rhabdomyolysis.

**Coagulopathy/Disseminated Intravascular Coagulopathy**

Therapy for coagulopathy is directed at treatment of the underlying disease process. However, if hemorrhagic complications occur, therapy with platelets, vitamin K, and fresh frozen plasma may be necessary.

**Compartment Syndrome**

Clinicians should monitor compartment pressures in the patient with suggested or existing compartment syndrome. When compartmental pressure exceeds 30 to 35 mm Hg, fasciotomy should be strongly considered, although the decision to perform a fasciotomy must be decided on a case-by-case basis. The failure of CK levels to decline appropriately suggests ongoing muscle injury from a compartment syndrome (Fig. 125-3).

**DISPOSITION**

No good prospective studies support a standardized approach to disposition of the patient with rhabdomyolysis. The high
risk for renal failure, however, mandates close monitoring of renal function, electrolytes, and hydration status, which usually requires admission to the hospital. Also, if the patient is a victim of trauma, serial CK levels should be followed to assess for ongoing muscle injury. If the patient is not a victim of trauma or compression injury, the underlying etiology of the rhabdomyolysis requires investigation to prevent recurrences.

**KEY CONCEPTS**

- Classic clinical manifestations of rhabdomyolysis include myalgias, weakness, and tea-colored urine. Because only half of patients present classically, the emergency physician should consider rhabdomyolysis in patients at risk, particularly when they present with an altered sensorium.
- Alcohol abuse, illicit drug use, certain medications, muscle overexertion, and traumatic muscle compression are the most common causes of rhabdomyolysis.
- In rhabdomyolysis, urine dipstick testing is strongly positive for blood, with few, or no, RBCs on microscopic examination. The diagnosis is confirmed by an elevated serum CK level.
- Early fluid resuscitation resulting in a urine output of 200 to 300 mL/hr reduces the risk of rhabdomyolysis-induced renal failure. Intravenous fluids are the primary treatment, with mannitol and urine alkalinization as adjuncts of unproven benefit. Loop diuretics should not be used since they can acidify the urine.
- Hyperkalemia can precipitate malignant cardiac dysrhythmias and must be treated promptly.
- To avoid exacerbating the hypercalcemia, which normally occurs during the recovery period when excess intracellular calcium shifts into the extracellular space, initial asymptomatic hypocalcemia should not be corrected.
- CK levels that do not decrease or continue to rise beyond 48 hours may indicate continued muscle injury and warrant a careful evaluation for compartment syndrome.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Hyperthyroidism, hypothyroidism, and adrenal insufficiency are endocrine disorders that often manifest with chronic, non-specific symptoms such as fatigue, weakness, and depression, and as a result are difficult to recognize in a typical medical encounter. With increased severity, each disorder has classic clinical manifestations that are more easily recognizable. Most importantly for the emergency physician, acute stresses can precipitate life-threatening illnesses in these patients, requiring vigorous medical management based on clinical judgment and suggestive laboratory data alone.

**HYPERTHYROIDISM**

**Perspective**

**Background and Epidemiology**

Although the terms hyperthyroidism and thyrotoxicosis are often used interchangeably, hyperthyroidism refers to conditions in which the production of thyroid hormone is increased, whereas thyrotoxicosis is defined as any state in which thyroid hormone levels are increased in the blood, whether it be from overproduction (Graves’ disease, toxic multinodular goiter [TMG]), thyroid hormone release from an injured gland (thyroiditis), or exogenous thyroid hormone. The clinical spectrum of hyperthyroidism is a continuum from asymptomatic or subclinical disease to life-threatening thyroid storm.

On large random population screenings, the prevalence of hyperthyroidism is 0.5 to 2.2%, with more than half of these patients considered subclinical (prehyperthyroid state with depressed thyroid-stimulating hormone [TSH] and normal tetraiodothyronine, thyroxine [T4]). The prevalence of hyperthyroidism in women is tenfold greater than in men.

Graves’ disease is the predominant cause of thyrotoxicosis, with TMG becoming more common with increasing age, exceeding Graves’ disease by 2 to 1 in patients older than 55 years. Hyperthyroidism is rare in childhood, but when seen is related to Graves’ disease. It is estimated that 1 to 2% of patients with thyrotoxicosis will progress on to thyroid storm when an acute intercurrent stress supervenes.

**Principles of Disease**

The follicular cells of the thyroid gland produce T4 and triiodothyronine (T3), which are regulated by a feedback loop with the anterior pituitary gland, which produces TSH. If levels of T4 drop, TSH production is stimulated, whereas if the T4 level is high, TSH is suppressed. TSH is in turn regulated by the hypothalamus’s production of thyrotropin-releasing hormone (TRH).

Thyroid hormone synthesis by the follicular cells starts with the production of thyroglobulin, a large hormonal precursor protein with numerous tyrosines in its structure. Iodine is then actively transported into follicular cells where it is oxidized and then bound to tyrosine residues. Linking of iodotyrosines within thyroglobulin produces T4 and T3, which are released into the circulation by proteolysis. All of T4 is produced in the thyroid gland, whereas only 15 to 20% of T3 is synthesized directly; the remainder is formed by deiodonation of T4 in peripheral tissues. During systemic illness, deiodonation occurs, but at an inner ring of T4, rather than the outer ring, and reverse T3 is produced. T4 is a prohormone with only mild intrinsic activity, whereas T3 is the biologically active hormone, and reverse T3 is inactive. Over 99.5% of thyroid hormones are protein-bound in the serum to thyronine-binding globulin (TBG) and other proteins, rendering them metabolically inactive. As a result, only free T4 and free T3 are clinically relevant.

Although iodide is a substrate for thyroid hormone production, excess iodide inhibits iodide trapping and thyroglobulin iodination (the Wolff-Chaikoff effect) and most importantly blocks the release of thyroid hormone from the gland. Iodide’s inhibition of thyroid hormone production and release is transient, with the gland escaping inhibition after 10 to 14 days. In contrast, an iodide load can induce hyperthyroidism (Jod-Basedow effect) in some patients with multinodular goiter and latent Graves’ disease, especially if the patient is iodine-deficient to begin with.

Thyroid hormone has effects on the metabolism of all tissues, exerting these at several levels. Thyroid hormone regulates gene activity by interaction at nuclear receptors. It has direct effects on metabolism by interaction with cellular enzymes, like adenosine triphosphatase. Most importantly, T3 and T4 increase the number and sensitivity of beta-adrenergic receptors, dramatically increasing response to endogenous catecholamines.

Graves’ disease is the most common cause of thyrotoxicosis and consists of the syndrome of hyperthyroidism, a diffuse symmetrical goiter, ophthalmopathy, and dermopathy. Graves’ disease primarily affects females between the ages of 20 and 40 years, often those with a family history of thyroid disease. It is an autoimmune disorder in which B lymphocytes produce...
immunoglobulins that stimulate the TSH receptor (thyroid-stimulating immunoglobulin [TSI]). The eye disease that accompanies the disease is thought to result from thyroid antibodies sensitized to common antigens in orbital fibroblasts and muscle.4,6

TMG is the second leading cause of hyperthyroidism, characterized by multiple autonomously functioning nodules typically developing in women older than 50 years of age. It is unusual in youth unless the patient has a preexisting nontoxic multinodular goiter or lives in a region of iodine deficiency. The population of the United States is generally iodine-sufficient, but areas of the world with populations that are deficient include Central America, South America, the Himalayas, Eastern Europe, and Central Africa. The hyperthyroidism in TMG is milder than Graves’ disease and is gradual in onset, but acute presentations can occur when iodine replacement is given to an iodine-deficient individual. Because of the age of the patients, cardiovascular manifestations like atrial fibrillation and heart failure predominate, whereas tremors and hypermetabolic features are less pronounced than Graves’ disease. Muscle wasting and weakness is common, and the patient is often described as apathetic. As multinodular goiters often extend retrosternally, obstructive symptoms may occur.9,10

A single hyperfunctioning (hot) nodule referred to as a toxic adenoma may occur in this same population, but it is less common than the multinodular form.

In thyroiditis, acute thyrotoxicosis can result from thyroid gland inflammation and cell breakdown with release of preformed thyroid hormone. Thyroiditis may be autoimmune in origin, infectious, or drug-induced. Hashimoto’s thyroiditis is the most common type of thyroiditis. It is an autoimmune disorder characterized by thyroid antibodies and lymphocytic infiltration of the thyroid gland. Patients present with painless goiter and hypothyroidism, but thyrotoxicosis is rarely evident early in the disease (hoshitoxicosis).11

Related autoimmune disorders of the thyroid include postpartum thyroiditis and sporadic thyroiditis. They are also referred to as painless, or silent, thyroiditis due to their small nontender goiter and mild symptoms. Five to 10% of pregnant women develop transient thyrotoxicosis 1 to 6 months postpartum, followed by a hypothyroid state for up to 6 months, then a return to baseline. There is a 70% chance of recurrence in subsequent pregnancies, and some women develop permanent hypothyroidism. Sporadic thyroiditis, which may account for up to 1% of thyrotoxicosis, is a similar entity, except for its lack of association with pregnancy.12

Subacute thyroiditis (de Quervain’s thyroiditis) appears to be a viral or postviral disease that presents with a prorome of fatigue, myalgias, and pharyngitis, followed by fever and severe anterior neck pain. Pain often radiates to the jaw and ears, and the gland is exquisitely tender. Symptoms of hyperthyroidism with sweating, palpitations, and tremor develop during this acute painful phase and may last several weeks, transitioning to a hypothyroid state for several months, then a return to a euthyroid state. Subacute thyroiditis may account for 2% of thyrotoxic patients and as is the case for other thyroid diseases, women predominate.13

Suppurative thyroiditis is a rare disorder that also presents with fever and anterior neck pain, but is marked by neck swelling, induration, and erythema and the presence of dysphonia and dysphagia. The cause is usually bacterial infection with abscess formation, but parasites, mycobacteria, and fungi may be responsible. Most patients have preexisting thyroid disease and are immunocompromised (AIDS).14

In North America, about 2% of patients treated with amiodarone develop thyrotoxicosis (higher in areas of iodine deficiency). Most of these cases result from a destructive thyroiditis, but a minority are due to amiodarone’s iodine load (400 times the daily requirement), which may unmask hyperthyroidism in patients with multinodular goiter and subclinical Graves’ disease. An exacerbation of the tachyarrhythmia that the patient is being treated for or heart failure is the typical presentation of a patient with thyrotoxicosis related to amiodarone. Other drugs that may induce thyroiditis include interferon, interleukin-2, granulocyte-macrophage colony-stimulating factor, and lithium.12,15,16

Chronic excess ingestion of thyroid hormone can result in thyrotoxicosis, referred to as thyrotoxicosis factitia. Although iatrogenic or patient errors may be responsible, medical personnel with psychiatric disease account for the majority of reported cases. Inadvertent ingestion of thyroid hormone in herbal products for weight reduction or in contaminated ground beef has been reported as well. Surprisingly, acute ingestions of thyroid hormone usually manifest only minor toxicity. The reasons for this are multiple: the 7-day half-life of T₄, the suppression of T₄-to-T₃ conversion and inhibition of endogenous hormone production by negative feedback loops, and the down-regulation of thyroid hormone receptors.17,18

A variety of rare forms of thyrotoxicosis have been described, including struma ovarii, thyroid carcinoma, hydatidiform mole, choriocarcinoma, and TSH-secreting pituitary adenomas4,6,19 (Box 126-1).

### Clinical Features

The symptoms and signs of thyrotoxicosis are caused by a hypermetabolic state and increased beta-adrenergic activity. Clinical manifestations vary from minimal (apathetic hyperthyroidism) to life-threatening (thyroid storm) and depend on the patient’s age, duration of disease, the level and rate of rise of hormone levels, drug interactions, and the stress of intercurrent illness. Hyperadrenergic manifestations are often masked in the elderly. Thyrotoxicosis of long duration and gradual course may go unnoticed by many patients, or symptoms may be attributed to other causes like emotional stress, dieting, or physical deconditioning.4,6

hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.
Constitutional symptoms such as fatigue and generalized weakness are very common in thyrotoxicosis. Despite increased calorie intake, weight loss is seen in most patients, averaging about a 15% drop from baseline. To confound things, elderly patients often have a decreased appetite, leading to a suggestion of occult cancer. Hypermetabolic symptoms like heat intolerance, excessive sweating, and preference for the cold are most pronounced in younger patients.

Neuropsychiatric complaints include anxiety, restlessness, tremor, feeling jittery or unable to sit still, insomnia, memory loss, and poor attention span. Family members often report emotional lability and agitation, which may progress to altered mental status and coma in thyroid storm. Weakness and fatigue of proximal muscle groups may result from thyroid myopathy, with patients often complaining of difficulty combing their hair, climbing stairs, or rising from a chair. A sudden and profound muscle weakness progressing to flaccid paralysis is described in a thyrotoxic variant of hypokalemic periodic paralysis.

Cardiopulmonary symptoms are very common and include palpitations, dyspnea on exertion, and reduced exercise tolerance. Older patients may present with new-onset angina, atrial fibrillation, or congestive heart failure as the presenting and only symptoms of thyroid disease.

Gastrointestinal complaints often include more frequent bowel movements, but not diarrhea. Dysphagia may result from enlargement of the thyroid gland in Graves’ disease or retrosternal extension of the gland in TMG. Nausea and vomiting may be seen with severe thyrotoxicosis.

Reproductive endocrine function can be affected. Women often complain of a change in their menses, anywhere from amenorrhea to menometrorrhagia, and infertility is very common. Men may complain of a decrease in libido and breast swelling.

Ocular complaints may result from ophthalmopathy in Graves’ disease, but not in other causes of thyrotoxicosis. A sense of irritation and excessive tearing are early symptoms, with diplopia, retrobulbar discomfort, blurring of vision, and foreign body sensation occurring late in the disease (Box 126-2).

Physical examination of the thyrotoxic patient may reveal distinctive findings, especially in younger individuals. The patient often appears anxious and fidgety, with a fine tremor of the hands and tongue and lightly closed eyelids. The skin feels warm, smooth, and velvety, likened to a baby’s skin, especially over the elbows. The face is rosy and blushed readily. The hands may reveal palmar erythema and the distal part of the nails may separate from the nail bed (onycholysis, or Plummer’s nails). Scalp hair is fine and brittle, and diffuse alopecia may occur.

Specifically in Graves’ disease, about 5% of patients develop marked thickening of the pretibial skin by mucopolysaccharide infiltration of the dermis (pretibial myxedema). These lesions are painless, raised nodules and plaques that become confluent over the pretibial area and dorsum of the feet. Hyperpigmentation and induration are present, but pitting is absent, and pretibial myxedema is always associated with Graves’ eye disease.

Tachycardia is seen in virtually all patients, and there is widening of the pulse pressure with bounding pulses. The apical impulse is prominent and the heart sounds are enhanced. A systolic flow murmur is usually present, and rarely a friction rublike sound along the left sternal border (Means-Lerman scratch) may also be heard. Atrial fibrillation can be seen at any age in hyperthyroidism, with an overall prevalence of 2%, but the frequency is age-dependant, rising to 15% in patients older than 70 years.

Even subclinical hyperthyroidism appears to increase the prevalence of atrial fibrillation threefold over that in the average population.

The ventricular response in thyrotoxic atrial fibrillation may be unusually fast, and the patient may be resistant to attempts to slow the rate as well as to convert to sinus rhythm. The chronic tachycardia and high cardiac output state in hyperthyroidism may lead to dilated cardiomyopathy, especially in elders and those with atrial fibrillation, resulting in an S1 gallop and basilar crackles. Primary pulmonary hypertension, sometimes associated with tricuspid regurgitation and right heart failure, may also be seen.

The characteristic stare of thyrotoxicosis results from retraction of the upper and lower eyelids revealing a rim of sclera beyond the limbus. As the eyelids are sympathetically innervated, the increased sensitivity to adrenergic stimuli in thyrotoxicosis leads to the widening of the palpebral fissures. Other hyperadrenergic eye findings in thyrotoxic patients include lid lag and globe lag. In lid lag, the upper lid lags behind the globe when the patient is asked to look slowly downward. In globe lag, the globe lags behind the upper lid with slow upward gaze.

Although stare is frequent in any form of thyrotoxicosis, proptosis of the globe is unique to Graves’ disease, resulting from mucopolysaccharide infiltration and inflammation of the ocular muscles and soft tissue leading to exophthalmos. Imaging with ultrasound, computed tomography, or magnetic resonance imaging reveals orbital swelling in virtually all patients with Graves’ disease, but only about 50% have clinical findings. Conjunctival injection, periorbital edema, and chemosis are early findings. Proptosis is defined by the anteroposterior distance from the lateral orbital ridge to the anterior cornea as greater than 20 mm. Progressive orbital involvement may lead to infiltration of the inferior rectus muscle with limitation of upward gaze. Very late findings can include keratitis from inability to close the eyes completely, and visual loss from optic nerve compression. Treatment of hyperthyroidism, especially with radioactive iodine, may paradoxically aggravate Graves’ eye disease.

Chronic proximal muscle wasting and weakness may result from thyrotoxic myopathy. More acute weakness with flaccidity may occur in Asian and Latino males from the thyrotoxic form of hypokalemic periodic paralysis.

Most thyrotoxic patients have a palpable abnormality on examination of the thyroid gland. In Graves’ disease, the gland is often two to three times normal size, but may be massively enlarged. A normal-size gland is unusual in younger patients, but more than 20% of older patients lack a goiter.
gland in Graves’ disease is symmetrical, smooth, soft to rubbery consistency, and has no evident nodules. In severe disease a palpable thrill and audible bruit are present and are usually continuous, rather than the systolic bruit seen with vascular disease. In TMG, the gland is variably enlarged and although multiple irregular nodules are often palpable, a single dominant nodule is not unusual, making distinguishing TMG from toxic adenoma difficult. The multinodular goiter may extend retrosternally, hiding it on examination unless the supraclavicular area is palpated on swallowing. By mass effect, a multinodular goiter may cause tracheal deviation and hoarseness as well as facial and neck vein engorgement, the latter becoming evident when the arms are elevated above the head (Pemberton’s sign)9,10 (Box 126-3).

In subacute thyroiditis, the thyroid gland is excessively tender, but redness or warmth of the overlying skin is only seen in supplicative thyroiditis. In the more typical entities of sporadic, postpartum, and Hashimoto’s thyroiditis, the gland is nontender with modest to no enlargement.11-14 In factitious thyrotoxicosis, the gland may be atrophic but this may be difficult to appreciate.

**Thyroid Storm**

Thyroid storm is a life-threatening decompensation of poorly controlled, untreated, or unrecognized thyrotoxicosis. It occurs in 1 to 2% of thyrotoxic patients and in about 10% of patients hospitalized for hyperthyroidism. Thyroid storm occurs predominately in Graves’ disease, but occasionally is seen in TMG and toxic adenoma.32,33 Occurrences in thyroiditis,34 factitious thyrotoxicosis,38 struma ovarii, hydatidiform mole,19 and other causes of thyrotoxicosis are limited to rare case reports.

Thyroid storm is an exaggeration of the clinical manifestations of thyrotoxicosis, further distinguished by the presence of fever, marked tachycardia, central nervous system dysfunction, and gastrointestinal symptoms. Decompensation of one or more organ systems, such as shock or heart failure, also defines thyroid storm. If untreated, thyroid storm is uniformly fatal, and even with aggressive management it still carries a 20% mortality rate.6,32,36,37

**BOX 126-3 PHYSICAL FINDINGS IN THYROTOXICOSIS**

- **Vital Signs:** Tachycardia, widened pulse pressure, bounding pulses, fever
- **Cardiac:** Hyperdynamic precordium, systolic flow murmur, prominent heart sounds, systolic rub (Means-Lerman scratch), tricuspid regurgitation, atrial fibrillation, evidence of heart failure
- **Ophthalmologic:** Widened palpebral fissures (stare), lid lag, globe lag, conjunctival injection, periorbital edema, proptosis, limitation of superior gaze
- **Neurologic:** Fine tremor, hyper-reflexia, proximal muscle weakness
- **Psychiatric:** Fidgety, emotionally labile, poor concentration
- **Dermatologic:** Warm, moist, smooth skin; fine, brittle hair; alopecia, flushed facies; palmer erythema; hyperpigmented pretibial plaques, nodules, or induration that is nonpitting; onycholysis
- **Neck:** Diffuse symmetrical thyroid enlargement, sometimes with a bruit and palpable thrill; thyroid with multiple irregular nodules or a prominent single nodule; tracheal deviation, venous prominence with arm elevation (Pemberton’s sign)

---

Central to the pathophysiology of thyroid storm is an increase in catecholamine-binding sites and hence a heightened response to adrenergic stimuli. Superimposed on this vulnerable state is an acute stress that causes an outpouring of catecholamines that in conjunction with high levels of free T₄ and T₃ precipitates the exaggerated response we call thyroid storm.4,6,37 It was once thought that thyroid storm resulted from a sudden dumping of thyroid hormone into the circulation, but except for sudden cessation of antithyroid therapy in a hyperthyroid patient and blunt or penetrating trauma to the thyroid gland (in both hyperthyroid and euthyroid patients) in which hormone leaks from injured acini, rapid rises in T₄ and T₃ are not responsible for storm.38-41 In fact, hormone levels in thyroid storm are not generally distinguishable from poorly controlled thyrotoxicosis.37

Infection and sepsis are the most common precipitants of thyroid storm, but as fever is a prominent feature of storm, the thyrotoxic state may be overlooked. Historically, thyroid and nonthyroid surgery have been the leading triggers of thyroid storm, but identification and treatment of thyrotoxicosis pre- operatively has dramatically decreased this as a precipitant. Other common precipitating events include myocardial infarction, stroke, pulmonary embolism, diabetic ketoacidosis, parturition, trauma, and administration of iodinated contrast media and amiodarone (Box 126-4).

The clinical presentation of thyroid storm is often dramatic. Although many of the findings of thyrotoxicosis are evident on

exam, certain features distinguish thyroid storm. Fever out of proportion to the physician’s expectations is characteristic of storm, sometimes mimicking heatstroke with temperatures exceeding 106°F. Inappropriately excessive diaphoresis is frequently observed, and sinus tachycardia over 140 beats per minute is common. Heart rates exceeding 150 beats per minute may be indicative of atrial fibrillation or other supraventricular tachycardias. In addition, symptoms and signs of congestive heart failure often accompany such rapid rates.

Altered mental status from metabolic encephalopathy is a hallmark of thyroid storm, ranging from restlessness and agitation to delirium, seizures, and coma.

Gastrointestinal symptoms are often pronounced, with nausea, vomiting, and diarrhea leading to volume depletion and hypotension. Abdominal pain mimicking bowel obstruction may be present. An unusual complication of severe thyrotoxicosis is cholestatic jaundice, which carries a bad prognosis if hepatic failure ensues.

Although hyperthermia, exaggerated tachycardia, and altered mental status can quickly identify possible thyroid storm, the clinical presentation can be difficult to differentiate from uncomplicated thyrotoxicosis. Taking into account the severity of fever, tachycardia, central nervous system dysfunction, congestive heart failure, and gastrointestinal symptoms, Burch and Wartofsky developed a scoring system to help distinguish uncomplicated thyrotoxicosis from impending thyroid storm and true thyroid storm (Table 126-1). Although this scoring system has not been rigorously tested, it may prove useful in decisions to treat in borderline cases.

### Diagnostic Strategies

The best screening tool for the diagnosis of thyrotoxicosis is the ultrasensitive TSH, which is depressed or undetectable in thyrotoxicosis. A normal TSH excludes hyperthyroidism and an elevated TSH is diagnostic for hypothyroidism, except in the rare circumstance of secondary hyperthyroidism from overproduction of TSH by a pituitary adenoma. Although a nondetectable TSH is specific for thyrotoxicosis, a modest depression of the TSH measurement is not always the result of mild or subclinical hyperthyroidism. Severe systemic illness may depress TSH production, leading to low levels of TSH, free T3, and free T4. This nonthyroidal illness pattern is often referred to as the euthyroid sick syndrome, and it appears to be a transient form of central hyperthyroidism, an adaptive response to slow metabolism during systemic stress. Chronic conditions in which TSH may be suppressed include anorexia nervosa, depression, and renal failure. Medications, including dopamine, glucocorticoids, somatostatin, and octreotide, may also depress TSH levels.

Although screening for thyroid disease with TSH is a reasonable strategy, measurement of thyroid hormone levels is required for a definitive diagnosis. Total T3 and total T4 assays may be misleading as they are influenced by changes in TBG. Increases in TBG with resultant false elevations in total T3 and T4 are seen in pregnancy, infectious hepatitis, and drug therapy with estrogens, tamoxifen, methadone, or heroin. In contrast, decreases in TBG with subsequent low total T3 and T4 are seen in cirrhosis, malnutrition, and nephrotic syndrome, as well as treatment with androgens or glucocorticoids. Lastly, many drugs inhibit the binding of T3 and T4 to TBG, thus resulting in higher levels of free T3 and free T4 levels, which will not be reflected in the total hormone measurements. Such drugs include salicylates, nonsteroidal anti-inflammatoryatories, heparin, furosemide, diphenylhydantoin, carbamazepine, and sulfonyleureas. Because of the many limitations in the measurement of total hormone levels, only free T3 and free T4 assays should be relied on.

The combination of both free T4 and free T3 elevation with TSH suppression is diagnostic of thyrotoxicosis. If TSH is suppressed and free T4 is normal, subclinical hyperthyroidism is likely; however, about 5% of patients with thyrotoxicosis have an elevated free T3 and normal free T4—referred to as T3 toxicosis, an entity more common in TMG. The reverse situation, in which free T3 is normal and free T4 is elevated may be seen in thyroiditis, exogenous levothyroxine ingestion, and hyperthyroidism in the elderly, often with suppressed T4 to T3 conversion due to comorbid illness (Table 126-2).

Differentiating Graves’ disease from other forms of thyrotoxicosis is usually straightforward clinically, but the measurement of thyroid antibodies to thyroglobulin and thyroid peroxidase may be helpful in questionable cases.

In addition to thyroid function tests, multiple laboratory abnormalities may be seen in thyrotoxicosis and thyroid storm. Hyperglycemia is the most common abnormality, seen in up to half the patients, likely related to glycogenolysis and catecholamine-mediated antagonism of insulin. Mild hypercalcemia is seen in 10% of patients and is related to hormone-mediated bone resorption, osteoporosis, and increased fracture risk.

T₄, triiodothyronine; T₃, thyroxine; TSH, thyroid-stimulating hormone.

Abnormal liver function tests are frequent in hyperthyroidism. The abnormalities observed include mild increases in serum aspartate transaminase, alanine transaminase, lactate dehydrogenase, bilirubin, and, most commonly, alkaline phosphatase. Although elevated serum bilirubin occurs in hyperthyroidism, clinical jaundice develops infrequently. Other abnormalities may include a leukocytosis with a left shift, a mild normocytic normochromic anemia, and low serum cholesterol levels.

The diagnostic evaluation for thyroiditis is more difficult. If there is exquisite gland tenderness and a sedimentation rate greater than 100, the diagnosis of subacute thyroiditis is likely. Other forms of thyroiditis, however, lack these findings. Doppler ultrasound of the thyroid may be helpful in differentiating among the hypervascular enlarged gland of Graves’ disease, the nodules of TMG, and thyroiditis or factitious thyrotoxicosis (decreased Doppler flow). Another option is a radioactive iodine uptake, which is depressed in thyroiditis and factitious thyrotoxicosis but increased in hyperthyroidism. If exogenous thyroid hormone abuse is suggested, measurement of thyroglobulin levels may confirm the diagnosis, being very low in factitious thyrotoxicosis and elevated in all other forms of thyrotoxicosis.

Differential Considerations

The overtly thyrotoxic patient is often thought to be very anxious, manic, or in the midst of a panic attack. In addition, hyperadrenergic signs may suggest sympathomimetic (cocaine, amphetamine) or anticholinergic intoxication or a withdrawal syndrome (alcohol, narcotics, sedative-hypnotics). The high fever and altered mental status seen in thyroid storm may mimic heatstroke, neuroleptic malignant syndrome, serotonin syndrome, bacterial meningitis, and sepsis.

In elders, the hyperadrenergic features of thyrotoxicosis may be masked, facial muscles may lack expression, and mental status may be depressed leading to the syndrome of apathetic hyperthyroidism. Patients with multinodular goiters and those older than 70 are most likely to present in this manner. New-onset atrial fibrillation and congestive heart failure exacerbations are often the presenting symptoms of apathetic hyperthyroidism. In addition, elders with thyrotoxicosis may have significant weight loss without increased appetite, suggestive of occult cancer.

Management

Patients with mild thyrotoxicosis with minor symptoms can often await outpatient follow-up for initiation of treatment. Of more importance to the emergency physician is the avoidance of interventions that may increase thyroid hormone levels or accentuate adrenergic stimuli. Thyrotoxic patients should not receive iotcontast media or amiodarone, both of which present an iodine load that may enhance thyroid hormone production. Caution is advised with the use of aspirin and nonsteroidal anti-inflammatories as they may interfere with protein binding of thyroid hormone, leading to increases in free T₄ and T₃. Drugs such as pseudoephedrine, ketamine, and albuterol that increase sympathomimetic tone should also be used with caution. Patients with thyrotoxicosis who are symptomatic may require initiation of beta-blocker therapy in the emergency department, but the initiation of thionamides like propylthiouracil (PTU) and methimazole are rarely indicated.

The prompt recognition and treatment of thyroid storm is crucial for patient survival. Therapeutic interventions have several aims: (1) reducing production of thyroid hormone, (2) inhibiting thyroid hormone release, (3) blocking peripheral conversion of T₄ to T₃, (4) initiating beta-adrenergic blockade, (5) instituting general supportive measures, and (6) identifying and treating the precipitating event.

Reducing Production of Thyroid Hormone

The first-line treatment of thyroid storm is the use of thionamides, which inhibit oxidation and organic binding of iodine to thyroglobulin, thus blocking synthesis of thyroid hormone. PTU and methimazole are available, but PTU is preferred due to its additional effect of impairing conversion of T₄ to T₃. PTU is given as an initial loading dose of 600 to 1000 mg by mouth, followed by 200 to 250 mg every 4 hours. The recommended dose for methimazole is 20 to 25 mg initially with the same dose repeated every 4 hours. If a patient cannot take medication orally, the same dose can be given by nasogastric tube or by retention enema. Such solutions require pharmacy preparation on a case-by-case basis. Due to solubility limitations, there is no IV form of PTU or methimazole, yet methimazole has been tried intravenously. Such solutions also require pharmacy preparation, and can be administered 30 mg every 6 hours. The intravenous (IV) route should be considered only in a dire situation where oral or rectal administration is not feasible or ineffective (Box 126-5).

Inhibiting Thyroid Hormone Release

Although thyroid hormone synthesis can be stopped by thionamides, preformed hormone in the gland is still available for release. Inorganic iodine blocks the release of thyroid hormone stored in the gland, but administration should be delayed at least 1 hour after PTU or methimazole is started. The reason for this delay is that an iodine load presented to an actively synthesizing gland provides further substrate for hormone production and release. Iodine is given as saturated solution of potassium iodide (SSKI) 5 gtt every 6 hours or Lugol’s solution 8 gtt every 6 hours. Published dosage recommendations range from one-half to double these doses, yet the effective iodine dose appears to be just a fraction of these numbers. As there is no apparent harm in administering larger iodine doses, this middle figure is most commonly recommended.

Because no IV form of iodide is available, the rectal route can be used if the oral or nasogastric route cannot be used. If allergy to iodine is encountered, lithium is an alternative agent.
Inhibition of Thyroid Hormone Synthesis
Propylthiouracil 600–1000 mg loading dose, then 200–250 mg every 4 hr
OR
Metimazole 20–25 mg initially, then 20–25 mg every 4 hr
(Preferred route: PO or NG. Alternative route: PR. Enema prepared by pharmacy. Same dose for all routes. No IV preparation is available, but IV metimazole can be prepared with the use of a Millipore filter and given 30 mg every 6 hr)

Inhibition of Thyroid Hormone Release
Saturated solution of potassium iodide (SSKI) 5 gtt by mouth, NG, or PR every 6 hr
OR
Lugol's solution 8 gtt by mouth, NG, or PR every 6 hr
OR
Sodium Iodide 500 mg in solution prepared by pharmacy IV every 12 hr
OR
If allergic to iodine, lithium carbonate 300 mg by mouth or NG every 6 hr

Beta-adrenergic Blockade
Propanolol 60–80 mg PO every 6 hr
OR
Metoprolol 50 mg PO every 6 to 12 hr
If IV route required, propanolol 0.5–1.0 mg IV slow push test dose, then repeat every 15 min to desired effect, then 2–3 mg every 3 hr

CHF, congestive heart failure; D₂/0.9NS, 5% dextrose in 0.9% normal saline; IV, intravenous; NG, nasogastric; PO, by mouth; PR, in rectum; T₃, triiodothyronine; T₄, thyroxine.

that impairs thyroid hormone release. The lithium dose is 300 mg every 6 hours by mouth or nasogastric tube, but lithium levels should be monitored to maintain a level of about 1 mg/L. Iodine should not be used in amiodarone-induced thyrotoxicosis as iodine overload may contribute to amiodarone’s toxicity. In hyperthyroidism unmasked by iodine excess (iodinated contrast agents), lithium should be used to inhibit hormone release and further iodine administration avoided. Iodine’s effects cease after 2 to 3 weeks of therapy, thus a delayed exacerbation of hyperthyroidism may ensue unless adequate thionamide therapy has been maintained.

Blocking Peripheral Conversion of T₄ to T₃ and Initiating Beta-adrenergic Blockade
Blockade of peripheral hyperadrenergic activity by beta-blockers is a cornerstone of therapy in thyroid storm and symptomatic thyrotoxicosis. Propanolol has traditionally been the beta-blocker of choice because it blocks conversion of T₄ to T₃ and its nonselective effects also improve tremor, hyperpyrexia, and restlessness. Dosage recommendations vary from 20 to 120 mg by mouth at 6-hour intervals, with most authors suggesting 60 to 80 mg per dose. If the patient cannot take anything by mouth or rapid beta-blockade is desired while waiting for the oral dose to be effective, IV propanolol can be administered as a test dose of 0.5 to 1 mg over 10 minutes. A cautious start is recommended if there is evidence of severe heart failure or hypotension as there are rare case reports of cardiovascular collapse after propanolol administration in thyroid storm. If the patient tolerates the initial dose of propanolol, it can be repeated every 15 minutes until the desired effect is achieved, then transitioning to 3-hour intervals with 1 to 3 mg boluses. If there are contraindications or concerns about beta-blocker therapy, a short-acting agent such as esmolol may be prudent. Esmolol is usually started as a loading dose of 250 to 500 µg/kg, then continued as an infusion of 50 to 100 µg/kg/min. Beta₁-selective drugs like esmolol or metoprolol (50 mg every 6–12 hours) may be preferable in asthma patients, but if not tolerated, reserpine 0.5 mg orally every 6 hours could be considered, while monitoring for hypotension.

Corticosteroids are recommended in thyroid storm, because they inhibit peripheral conversion of T₄ to T₃, as well as block the release of hormone from the gland. The synergistic effect of PTU, iodide, and steroids in thyrotoxicosis can restore the concentration of T₄ to normal within 24 to 48 hours. Corticosteroids are also suggested due to an absolute or relative adrenal insufficiency that can occur in thyroid storm. Addison’s disease can occur concomitantly with Graves’ disease in polyglandular autoimmune syndrome type 2, but more importantly, the increased clearance of cortisol in thyrotoxicosis coupled with the high demand for cortisol in such critically ill patients leads to a relative adrenal insufficiency in most. Hydrocortisone can be given as an initial bolus of 100 to 300 mg IV, followed by 100 mg every 8 hours for several days. Dexamethasone has also been used in this setting as well, in doses of 2 to 4 mg every 6 hours or 8 mg every 24 hours.

Instituting General Supportive Measures
Supportive measures are equally important in the management of thyroid storm. Fluid resuscitation should be vigorous
unless clear signs of congestive heart failure are evident. Due to the depletion of glycogen stores in thyrotoxicosis, a 5% dextrose solution is recommended; hence for volume replacement, D5/0.9NS is a rational choice. As high fever to the point of heatstroke is not unusual in thyroid storm, therapy to dissipate heat is a priority, typically by means of cool mists, fans, ice packs, cooling blankets, and ice water lavage. Acetaminophen could be used for moderate fever, but as hepatic dysfunction may occur in storm, it should be used with caution. Aspirin is contraindicated in thyroid storm because it increases levels of free thyroid hormone.

Treatment to hasten elimination of thyroid hormone has been described. Cholestyramine, an anion exchange resin, binds thyroid hormone in the bowel lumen, thus interrupting enterohepatic recirculation. Cholestyramine in a dose of 4 g every 6 hours has been shown to result in a more rapid decline in hormone levels than thionamides alone. Colestipol has been shown to have a similar effect, but not ezetimibe. Progressive deterioration in a patient with thyroid storm, despite aggressive multidrug therapy, may lead to the consideration of plasmapheresis, plasma exchange, or dialysis to attempt rapid reduction in thyroid hormone levels.

Benzodiazepines for agitation and hypomania of thyrotoxicosis may be considered as the hyperadrenergic state resembles cocaine intoxication. t-Carnitine has been described in thyroid storm, its suggested mechanism being the inhibition of thyroid hormone entry into cell nuclei. The dose used is 1 g every 12 hours by mouth (Box 126-5).

Radioactive iodine or surgery has no role in the management of thyroid storm or thyrotoxicosis until a sustained euthyroid state has been achieved, as these interventions can precipitate storm themselves.

Beta-blockers are a mainstay in the treatment of high-output heart failure as defined by a normal or exaggerated ejection fraction on echocardiography. Preexisting heart disease aggravated by thyrotoxicosis may be associated with low-output congestive heart failure (low ejection fraction on echocardiography), in which circumstance caution should be exercised with the use of beta-blockers, because cases of cardiovascular collapse have been described with their use in this setting. Routine management with angiotensin-converting enzyme inhibitors, diuretics, and digoxin are appropriate in both groups.

The management of atrial fibrillation in thyrotoxicosis also has unique features. The rapid ventricular response generally requires high doses of beta-blocker for control. If thyroid storm is present, calcium channel blockers should be avoided as hypotension is a potential complication. Digoxin tends to be ineffective in this setting, but could be tried. Amiodarone should not be used due to its iodine load and potential to induce thyroiditis. Attempts to convert to sinus rhythm are usually fruitless while the patient remains thyrotoxic and thus should be postponed until the patient is euthyroid.

Pain and tenderness as seen in subacute thyroiditis is treated with nonsteroidal anti-inflammatories. If refractory or recurrent, prednisone may be required. Thyrotoxicosis in thyroiditis is usually mild, and beta-blockers alone are recommended. In fact, thionamides and iodine have no effect in thyroiditis. If drug-related, the offending agent (amiodarone, interferon) should be stopped immediately. Thyrotoxicosis from exogenous thyroid hormone ingestion should be treated with beta-blockade alone because the thyroid gland is shut down, thereby rendering thionamides and iodine ineffective. Cholestyramine could be used to bind hormone in the gut in both the acute and chronic intoxication, but evidence to its efficacy is limited (Box 126-6).

Special mention should be made regarding potential toxicity of thionamide therapy, as it may be a presenting manifestation of a thyrotoxic patient. The minor adverse reactions that occur in up to 5% of patients include drug fever, alteration in sense of taste, skin eruptions, arthralgias, and sialoadenitis. Such reactions should not lead to discontinuation of therapy in the patient with thyroid storm, but should be reason to stop in the mildly thyrotoxic individual. The most feared and life-threatening adverse reaction to PTU and methimazole is agranulocytosis, which is often heralded by onset of fever and severe sore throat. Any patient who develops fever while on thionamide therapy should have his or her white blood cell count determined and if at all depressed, therapy should be stopped immediately. Fortunately, such reactions occur only in 3 or 4 patients per 1000. Other infrequent yet serious reactions to thionamides include hepatitis, vasculitis, and polyarthritis.
Identifying and Treating the Precipitating Event

Simultaneous with the previously detailed treatment measures, an aggressive search for an underlying precipitant of thyroid storm should be undertaken. As infection is the most common culprit, a chest radiograph, urinalysis, and blood cultures are routine. Silent myocardial ischemia should be assessed by an electrocardiogram and troponin, and the possibility of stroke or pulmonary embolism considered. Empirical use of antibiotics are tempting in the setting of thyroid storm, but restraint is prudent unless there is strong clinical evidence.

Aggressive management of thyroid storm with PTU followed by iodine, beta-blockers, corticosteroids, fluid resuscitation, rapid cooling, and treatment of the precipitating illness can resolve fever, tachycardia, and altered mental status within a 24-hour period. All patients with storm should be admitted to an intensive care setting, and any interruption in therapy should be avoided as it can lead to a sudden recrudescence of symptoms and death.

**HYPOTHYROIDISM**

**Perspective**

The clinical presentation of the hypothyroid patient can vary from asymptomatic or subclinical cases to life-threatening myxedema coma. In random population sampling, the prevalence of TSH elevation has ranged from 3.7 to 9.5%, with the majority of these having a normal free T4, which by definition is subclinical hypothyroidism. Overt hypothyroidism (elevated TSH and depressed free T4) is seen in a minority of these patients, about 0.3% of the population overall, with the prevalence rising with age, such that patients older than 80 years have a fivefold greater likelihood of developing hypothyroidism than do 12- to 49-year-olds. Some surveys estimate the incidence of hypothyroidism as high as 20% in elders. The female to male ratio is about 4:3 in hypothyroidism, in contrast to 8:1 for hyperthyroidism. Race differences are notable in that hypothyroidism is seen in 5.1% of whites, 4.1% of Hispanic-Americans, and 1.7% of African-Americans.

**Principles of Disease**

The etiology of hypothyroidism includes primary thyroid failure, thyroiditis, pituitary/hypothalamic causes, drug-related and iatrogenic. The vast majority of hypothyroidism encountered in the United States is due to thyroid gland failure, and the majority of these are caused by autoimmune destruction of the gland in Hashimoto’s thyroiditis. In younger patients, the disease is associated with a goiter and elevated titers of antithyroid antibodies, specifically to thyroid peroxidase, thyroglobulin, and TSH. The TSH receptor antibody in Hashimoto’s disease blocks the receptor, in contrast to the stimulating antibody in Graves’ disease. In older patients, the thyroid gland is typically atrophic, and evidence of autoimmunity is often lacking.

End-stage Graves’ disease can also result in autoimmune destruction of the thyroid gland, occurring spontaneously following several exacerbations of hyperthyroidism. More commonly, hypothyroidism follows treatment of Graves’ disease with radioactive iodine or thyroidectomy.

Drug-induced hypothyroidism is often encountered with lithium carbonate because it inhibits hormone release. Iodine excess, as seen with amiodarone, iodinated contrast media, kelp supplements, and iodine-containing cough medicines, can impair thyroid hormone release and synthesis (Wolff-Chaikoff effect), thereby converting subclinical hypothyroidism to overt hypothyroidism and sometimes precipitating hypothyroidism de novo. In contrast, iodine-deficient patients administered an iodine load increase production of thyroid hormone and may develop hyperthyroidism. Interferon-alfa can result in hypothyroidism by precipitating Hashimoto’s thyroiditis. Overtreatment with PTU or methimazole may lead to hypothyroidism due to their inhibition of hormone synthesis. Phenytion, carbamazepine, phenobarbital, and rifampin may aggravate hypothyroidism by enhancing metabolism of thyroid hormone.

Patients on thyroid replacement therapy can develop hypothyroidism when drugs are introduced that interfere with hormone absorption, including iron, calcium, phosphate binders, sucrlate, aluminum hydroxide, cholestyramine, colestipol, and even coffee.

Iatrogenic causes of hypothyroidism include neck irradiation for cancer or lymphoma and thyroidectomy for nodular goiter or thyroid cancer.

Hypothyroidism may be seen as a late phase of thyroiditis. In Hashimoto’s disease the initial hyperthyroid phase is rarely identified, and hypothyroidism predominates. In subacute, silent, and postpartum thyroiditis the hyperthyroid phase is usually clinically evident, and the hypothyroidism is often very mild and transient, but can become chronic.

Rare causes of hypothyroidism include inherited disorders of hormone biosynthesis and central hypothyroidism. Central causes are usually due to pituitary destruction by an adenoma, hemorrhage (Sheehan’s syndrome), or infiltration (sarcoid, amyloid), but can also result from hypothalamic dysfunction.

A form of central hypothyroidism that appears to be an adaptive response to significant nonthyroidal illness is the euthyroid sick syndrome. Mild suppression of TSH release leads to a decrease in free T4 and T3. Impairment of T4 to T3 conversion also develops leading to elevation of reverse T3 levels. Euthyroid sick syndrome remits spontaneously with resolution of the acute illness, and treatment with thyroid replacement is not indicated. Drugs that may contribute to TSH suppression in nonthyroidal illness include glucocorticoids, dopamine, and octreotide (Box 126-7).

**Clinical Features**

Symptoms and signs of hypothyroidism are often very subtle and difficult to recognize in their milder presentation. Patients often ignore or tolerate symptoms when their development is very gradual, as is the case in Hashimoto’s thyroiditis, where the delay from symptom appearance and diagnosis may be several years. Acute hypothyroidism presenting over weeks to months may be seen in thyroiditis or withdrawal of exogenous thyroid hormone. Chronic disease may present acutely due to drug toxicity or when an intercurrent illness is superimposed.

The clinical manifestations of hypothyroidism result from changes induced by lack of thyroid hormone, most notably a generalized slowing of metabolic processes (due to altered gene expression and decreased catecholamine sensitivity) and an accumulation of glycosaminoglycans (decreased metabolism) in interstitial fluids.

Patients with hypothyroidism typically have pale, cool skin from decreased blood flow and fluid accumulation. Epidermal and sweat gland changes result in dry, scaly, rough skin. The skin is firm to the touch and appears swollen, but does not pit. In severe, chronic disease, the patient has a typical facies characterized by puffy eyelids, broad nose, swollen lips, and macroglossia. The hair in hypothyroidism becomes coarse and brittle, and alopecia is common. Thinning of the lateral third
of the eyebrows may occur. The nails also become brittle and thin. The skin may take on a yellowish tinge from carotene, which accumulates because of impaired conversion to vitamin A. Carotenemia is distinguished from jaundice by the sparing of the conjunctiva. Vitiligo may occur in association with polyglandular syndrome, whereas hyperpigmentation may be seen if the patient has concomitant Addison’s disease (Schmidt’s syndrome).  

Generalized edema of the face and extremities may develop—nonpitting from accumulation of glycosaminoglycans and pitting from a capillary leak phenomenon seen in hypothyroidism. A localized pretibial myxedema and exophthalmos may still be seen in patients with Graves’ disease rendered hypothyroid by surgery or radioactive iodine.  

The hypothyroid patient is usually normothermic, but complaints of cold intolerance and cool extremities are common. Blood pressure is usually normal, but 20 to 40% of patients have diastolic hypertension and narrowing of the pulse pressure. Bradycardia is common, but asymptomatic. In contrast to hyperthyroidism, in which atrial arrhythmias are frequently seen, hypothyroidism may be associated with QT prolongation and ventricular irritability. Patients with hypothyroidism often complain of dyspnea on exertion and decreased exercise capacity, and although decreased cardiac contractility and diastolic dysfunction is present in chronic hypothyroidism, signs of congestive heart failure are usually absent. Angina and coronary artery disease may be masked by slowed metabolism and decreased ischemic stress, but coronary disease is accelerated by elevations in cholesterol and blood pressure.

Pericardial effusions may be seen in chronic hypothyroidism, but are usually small and asymptomatic. Larger effusions may result in diminished heart sounds and decreased apical impulse, but cardiac tamponade is rarely seen due to slow chronic build up.  

Complaints of fatigue, dyspnea, and decreased exercise capacity are most likely to be from a respiratory origin, rather than cardiac. Hypothyroidism is characterized by impaired ventilator responses to hypercapnea and hypoxia, as well as myopathy of respiratory musculature, with resultant slow, shallow respirations. Macroglossia may contribute to the respiratory distress and lead to obstructive sleep apnea. Mucopolysaccharide infiltration or edema of the vocal cords leads to a deep, husky voice in the hypothyroid patient. Primary pulmonary hypertension is reported with increased prevalence in hypothyroidism and may contribute to complaints of dyspnea or chest pain.  

A modest weight gain is characteristic of hypothyroidism, but massive obesity is unusual. Limiting the anticipated weight gain in this hypometabolic state is a concomitant decrease in appetite.  

Neurocognitive impairment may be a presenting feature of hypothyroidism, especially in elders. Slowness of comprehension, lethargy, decreased attention span, poor short-term memory, and impaired abstract thinking may all be present. The patient generally appears placid or depressed, moves slowly and deliberately, and speaks hesitantly. Although unusual in hypothyroidism, extreme agitation, psychosis, and even seizures have been described—the last is referred to as myxedema madness or Hashimoto’s encephalopathy.  

Paresthesias are common in hypothyroidism and although peripheral polyneuropathy may occur, mononeuropathies are much more prevalent. Edema of perineural and synovial tissue within the carpal tunnel leads to carpal tunnel syndrome, which is reported in about 25% of hypothyroid patients. Another common mononeuropathy in hypothyroidism involves the eighth cranial nerve, resulting in sensorineural hearing loss and tinnitus.  

Muscle-related symptoms are frequent in hypothyroid patients, often manifesting with proximal muscle weakness, myalgias, stiffness, and fatigue. Hypothyroid myopathy leads to slowing of the relaxation phase of deep tendon reflexes, referred to as hung-up or pseudomyotonic reflexes. This reflex phenomenon is best demonstrated with the Achilles tendon reflex performed while the patient is kneeling on a chair. Hung-up reflexes are not unique to hypothyroidism, as they can be seen with aging, diabetes, and pregnancy. Muscle palsy in most patients is normal, but some with hypothyroid myopathy develop firm, enlarged muscles referred to as pseudohyptertrophy. Prolonged mounding of muscle mass may sometimes be evident when reflexes are elicited (myoedema). Ataxia and dysmetria reversible with thyroid replacement have been described, which may by myopathic or cerebellar in origin.  

Elevation of the serum creatine kinase (CK) concentration is seen in 70 to 90% of patients with hypothyroidism; however, the magnitude of the CK elevation does not correlate well with the severity of the patient’s myopathy or hypothyroidism. Rare cases of acute rhabdomyolysis have been reported in severe
hypothyroidism, precipitated by exercise, statin therapy, or renal failure.80

One of the most common complaints of the hypothyroid patient is constipation, which results from decreased bowel motility. Rarely, ileus or megacolon may occur and be confused with intestinal obstruction.

Although oligo- or amenorrhea may suggest a pituitary/hypothalamic origin, primary hypothyroidism can result in menstrual abnormalities due to altered metabolism of estrogen. Menorrhagia is also described. Decreased fertility and early abortions are commonly associated complaints. Hypothyroid men often report decreased libido, erectile dysfunction, and delayed ejaculation.62,63

Initial symptoms of hypothyroidism may be rheumatic in character. Arthralgias and stiffness, sometimes associated with noninflammatory joint effusions, may be seen. Acute monoarthritis may be seen due to an increased prevalence of hyperuricemia and gout in hypothyroid patients, and perhaps as a result of a minor link with pseudogout and chondrocalcinosis as well81,82 (Box 126-8).

Myxedema coma is a life-threatening decompensation of severe long-standing hypothyroidism, often precipitated by an acute illness or stress. The hallmarks of myxedema coma are altered mental status and hypothermia, but hypertension, bradycardia, and hypoventilation are often present as well. The typical patient is an elderly woman with chronic hypothyroidism that is untreated or unrecognized. Hashimoto’s thyroiditis is the most common underlying thyroid pathology due to its insidious nature, but any cause of hypothyroidism is possible. The history is one of progressive weakness, lethargy, and immobility that may progress to shock and death.

Virtually any acute illness may precipitate myxedema coma, but the most common factors include infection, cold exposure, trauma, cerebrovascular accident, congestive heart failure, gastrointestinal bleeding, and drug effects. Sedatives and narcotics are commonly implicated drug classes, but general anesthesia, thyroid hormone noncompliance, amiodarone, lithium, iodides, phenytoin, and rifampin may be factors33-64,83-85 (Box 126-9).

BP, blood pressure; HEENT, head, ear, eyes, nose, and throat.
Myxedema Coma: Aggravating or Precipitating Factors

- Infection/sepsis (especially pneumonia)
- Exposure to cold
- Cerebrovascular accident
- Drug effect
  - **Altered sensorium:** Sedative-hypnotics, narcotics, anesthetics, neuroleptics
  - Decrease T₄ and T₃ release: amiodarone, lithium, iodides
  - Enhance elimination of T₄ and T₃: phenytoin, rifampin
  - **Inadequate thyroid hormone replacement:**
    - Noncompliance; interference with absorption (iron, calcium, cholestyramine)
  - Myocardial infarction
  - Gastrointestinal bleeding
  - Trauma/burns
  - Congestive heart failure
  - Hypoxia
  - Hypercapnia
  - Hypoponatremia
  - Hyperkalemia
  - Hypercalcemia
  - Diabetic ketoacidosis

T₄, triiodothyronine; T₃, thyroxine.

It is important to appreciate that although infection is the most common precipitant of myxedema coma, the patient does not usually mount a febrile response due to the profound hypometabolic state. Peripheral vasoconstriction helps maintain core temperature in severe hypothyroidism, but this compensation may be tenuous. Hypothermia is characteristic of myxedema coma and it is usually marked, with body temperatures as low as 24°C (75°F) described. Temperatures below 90°F are common and carry a grave prognosis. In contrast to environmental hypothermia, shivering is often absent.63,75,85

Whereas diastolic hypertension is common in hypothyroidism, the blood pressure in myxedema coma is usually low and may be refractory to fluid resuscitation and pressors unless thyroid hormone is administered.76 Sinus bradycardia is routinely seen and may be unresponsive to atropine, but heart block is unusual. Prolongation of the QT interval with cases of torsades de pointes is described.70 Despite cardiac enlargement and decreased myocardial contractility seen in most patients, evidence of congestive heart failure is not common.62

Signs of severe hypothyroidism are usually evident in the myxedema coma patient. Dry, coarse skin; sparse, brittle hair; cool extremities; puffy eyelids and face; large tongue; hoarse voice; and slow, delayed speech and movement are typical. Pitting and nonpitting edema are prominent in the extremities.68 Pleural and pericardial effusions are common, and ascites may be present.70

Despite the name myxedema coma, most patients present with confusion, lethargy, or stupor and are not comatose, but progression to coma is inexorable if therapy is not instituted. The cause of altered mental status is multifactorial, including thyroid hormone deficiency, hypothermia, hypercapnea, hypoponatremia, hypotension, and hypoglycemia.75,85 Paradoxically, a more agitated, psychotic state may sometimes occur, referred to as myxedema madness.77 Focal or generalized seizures may occur in up to 25% of patients, and status epilepticus has been reported.75

Respiratory depression with carbon dioxide retention is common in myxedema coma, contributing further to the altered mental status. An enlarged tongue, supraglottic edema, and obesity further aggravate hypercapnea and hypoxia. Pneumonia, a common precipitant of myxedema coma, accelerates the downward spiral toward respiratory failure. Mechanically assisted ventilation is required in most patients, often leading to extended hospitalization74,85 (Box 126-10).

Diagnostic Strategies

The diagnosis of primary hypothyroidism requires the measurement of an elevated serum TSH and a depressed free T₄ level. If the index of suspicion is low, the serum TSH alone can be used as a screening test, and the free T₄ test only performed if the TSH is abnormal. The total T₄ level is not recommended in evaluating thyroid disease because of numerous confounding factors on protein binding that alter its measurement, thus the free T₄ is preferred. The serum T₃, whether total or free, should not be relied on in the diagnosis hypothyroidism due to its great variability. Almost any acute or chronic illness or physiologic stress can lead to depression of T₄ 5'-deiodinase activity, thereby leading to decreased peripheral conversion of T₄ to T₃ and an increase in reverse T₃ levels.7

The elevation of TSH accompanied by a normal free T₄ is referred to as subclinical hypothyroidism (SCH). The prevalence of SCH is 4 to 9% in large general population screening surveys and in 7 to 26% in geriatric series.1,2,62,87 Although by definition SCH is asymptomatic, this laboratory abnormality is associated with the development of depression, cognitive impairment, subtle systolic and diastolic dysfunction, and hyperlipidemia.86

The distinction of myxedema coma from moderate to severe hypothyroidism cannot be made by thyroid functions tests alone. Elevation of the serum TSH may be blunted by any concomitant systemic illness (hypothyroid sick syndrome), resulting in a misleadingly minor elevation in TSH in a severely hypothyroid patient. Central hypothyroidism is characterized by a low serum TSH together with a low free T₄ level. The euthyroid sick syndrome can have very similar results but the TSH is only mildly suppressed and the free T₄ is normal or slightly low. Because central hypothyroidism is usually not a chronic condition, many of the clinical findings of hypothyroidism are absent.75,73,86
Hyponatremia is a common electrolyte abnormality in severe hypothyroidism and myxedema coma, but it is not seen in milder forms of the disease. Hyponatremia results from decreased free water clearance due to diminished renal blood flow from volume depletion and depressed cardiac output as well as excess excretion of anti-diuretic hormone. A reversible elevation in serum creatinine is also seen in this setting.62,75,84

Hypoglycemia may also occur in severe hypothyroidism and myxedema coma. Decreased gluconeogenesis and reduced insulin clearance are the likely mechanisms, but it is important to recognize that a low blood sugar may be a clue of concomitant adrenal insufficiency, which is present in up to 10% of myxedema coma patients.

CK from a muscular origin is often elevated in severe hypothyroidism, but acute rhabdomyolysis is uncommon.80 Serum transaminases and lactate dehydrogenase are frequently elevated as well.

Lipid clearance is decreased in hypothyroidism, resulting in elevations of total cholesterol, low density lipoprotein, and triglyceride. In the Colorado Thyroid Disease Prevalence Study of 25,862 patients, euthyroid patients averaged a total cholesterol of 214 mg/dL, whereas subclinical and overt hypothyroid subjects averaged 224 and 251 mg/dL, respectively.1,3

Severe hypothyroidism may be associated with a normocytic, normochromic anemia from decreased red cell production and a depressed white blood count that does not rise appropriately in response to infection.75 Increased bleeding times may result from an acquired von Willebrand’s syndrome.

A chest radiograph may reveal an enlarged cardiac silhouette, but evidence of heart failure is unusual. Although myocardial hypertrophy may be present in hypothyroidism, cardiomegaly usually represents the presence of pericardial effusion, seen in 30 to 78% of severe, chronic disease, but less than 5% of mild hypothyroidism. Pleural effusions may be seen as well.62,72,73,75

Electrocardiographic findings include sinus bradycardia, nonspecific ST and T wave abnormalities, and decreased voltage or electrical alternans if a pericardial effusion is present. Prolongation of the QT interval and ventricular arrhythmias may be seen as well.59,70,75

Electrocardiographic findings include sinus bradycardia, nonspecific ST and T wave abnormalities, and decreased voltage or electrical alternans if a pericardial effusion is present. Prolongation of the QT interval and ventricular arrhythmias may be seen as well.59,70,75

If a lumbar puncture is performed to evaluate altered mental status, findings of increased opening pressure and an elevated cerebrospinal fluid protein level may be seen in myxedema coma.

### Differential Considerations

The overtly hypothyroid patient is often thought to be severely depressed, and the diagnosis of hypothyroidism may be overlooked. In fact, about 10 to 15% of patients hospitalized for depression are found to be hypothyroid. Roughly 25% of bipolar patients with a rapid cycling pattern are found to be hypothyroid. Even subclinical hypothyroid patients have more than twice the incidence of depression than euthyroid patients.76 The profound fatigue and weakness that may occur in hypothyroidism may be diagnosed as depression, chronic fatigue syndrome, Addison’s disease, or anemia.

Respiratory failure in patients with substrates of obstructive sleep apnea such as obesity, hypoventilation, and macroglucosia, should be evaluated for hypothyroidism. In addition, any patient with decreasing exercise capacity and dyspnea without any clear cardiopulmonary cause should be evaluated for hypothyroidism.

The hypothermia of myxedema coma may be attributed to environmental stress, sepsis, or hypoglycemia. The altered mental status, as well, may be attributed to concomitant conditions in myxedema coma, such as drug toxicity, hypothermia, hypercapnea, hypoxia, hypoglycemia, or hyponatremia, and the hypothyroidism overlooked.

### Management

The patient with a new diagnosis of overt or subclinical hypothyroidism generally does not require the initiation of treatment from the emergency department, yet it is important to be familiar with the principles of diagnosis and treatment. Before commitment to lifelong therapy, the serum TSH and free T4 should be repeated for confirmation. About 5% of patients with subclinical hypothyroidism normalize within 1 year and, of the remainder, approximately 5% per year develop overt hypothyroidism. Treatment with thyroid hormone replacement may be considered in SCH if symptomatic or the TSH is greater than 10.62,64,88

Levothyroxine (T4) is the mainstay of treatment of hypothyroidism. Treatment is generally started at a dose of 1.6 µg/kg/day in younger patients, whereas elders and patients with underlying coronary artery disease are often started at less than half that dosage due to their susceptibility to angina and arrhythmias. The long half-life of T4 (7 days) and its gradual conversion to T3, leads to dosage adjustments of 12.5- to 25-µg increments at no less than 6-week intervals.62,63

The management of myxedema coma requires immediate attention to airway management, fluid resuscitation, thyroid hormone replacement, general supportive measures, and treatment of the precipitating illness (Box 126-11).

### BOX 126-11 TREATMENT OF MYXEDEMA COMA

- Protect the airway/ventilatory support; monitor for alkalois
- Fluid resuscitation: 0.9NS or D5/0.9NS if hypoglycemia
- Watch for unmasking of CHF
- Thyroid hormone replacement: T3 alone (elderly and patients with cardiac comorbidity): T3 300–500 µg IV as initial bolus
- Or split bolus 200–300 µg IV day 1 and 2
- Then 50–100 µg IV daily until able to take PO
- T4 alone (younger patient, no cardiac risks; rapid correction desired): T4 10–20 µg IV initially, then 10 µg IV every 4 hr for 1 day, then 10 µg IV every 6 hr for 1–2 days
- Combination T3 and T4 therapy (intermediate approach): T4 200–250 µg IV as initial bolus
  - T3 10 µg IV initial dose, then 10 µg IV every 8–12 hr
  - T4 100 µg IV in 24 hr, followed by 50 µg/day
- Hydrocortisone
  - 50–100 mg IV every 6–8 hr
- Hyponatremia
  - Avoid hypotonic fluids, use only 0.9NS or D5/0.9NS if less than 120 mEq/L, consider 3% saline, 50–100 mL boluses
- Passive rewarming
  - Regular blankets, prevent heat loss
  - If heating blankets considered, pretreat with IV fluids and monitor BP closely
  - Avoid mechanical stimulation
  - Treatment of any precipitating illness, with special attention to infectious causes

BP: blood pressure; CHF, congestive heart failure; D5/0.9NS, 5% dextrose in 0.9% normal saline; IV, intravenous; T3, triiodothyronine; T4, thyroxine.
Airway Management

Prompt attention to the airway is critical, as there may be partial obstruction from macroglossia and supraglottic edema, myopathy of respiratory muscles, and central hypoventilation. Most myxedema coma patients require endotracheal intubation and prolonged ventilatory support. Blood gases should be monitored closely as life-threatening alkalosis can occur during the initial phase of full ventilator support.74

Fluid Resuscitation

Intravascular volume depletion is prominent in myxedema coma, even in the presence of normal vital signs. Fluid resuscitation should be started immediately, but the aggressiveness of administration should be tempered by the risk of unmasking congestive heart failure. The initial fluid of choice is D₅/0.9NS because the myxedema coma patient is at high risk for cardiac toxicity. T₄ is administered IV in half the loading dose by some authors to speed clinical response while minimizing peripheral conversion to T₃, which is a slow, delayed process. Proponents of T₃ administration suggest that the quicker onset involves the IV administration of T₄₀.9NS because the myxedema coma patient is at high risk for both hyponatremia and hypoglycemia.75,83-85

Thyroid Hormone Replacement

Prompt thyroid hormone replacement is critical for patient survival from myxedema coma, although the most effective regimen is unclear. Determination of the form of thyroid hormone (T₄ or T₃ or both) and the dosage must balance the high mortality of untreated myxedema coma against the risk of myocardial infarction or cardiac arrhythmias induced by therapy. T₄ has lower risk of toxicity as its action depends on peripheral conversion to T₃, which is a slow, delayed process. Proponents of T₃ administration suggest that the quicker onset of action and the increased biologic activity of T₃, as well as the impaired conversion of T₄ to T₃ in the critically ill, make T₃ the logical choice. High doses of T₄ or T₃ appear to increase mortality, hence there is a limit on how fast hormone replacement can be given.75,83-85

The most widely published approach to myxedema coma involves the IV administration of T₄₀.9NS because the myxedema coma patient is at high risk for both hyponatremia and hypoglycemia.75,83-85

For critically ill younger patients without cardiac disease, where a more rapid correction of hormone levels is desired, the use of T₃ alone should be considered. An IV loading dose of 10 to 20 µg, followed by 10 µg IV every 4 hours for 24 hours, followed by 10 µg every 6 hours for 1 to 2 days is suggested.75

An intermediate approach using both T₄ and T₃ is suggested by some authors to speed clinical response while minimizing cardiac toxicity. T₄ is administered IV in half the loading dose (200–250 µg) with 10 µg of T₃, followed by T₃, 10 µg every 8 to 12 hours, and maintenance T₄, 50 µg every 24 hours. Due to impaired oral absorption and transit of medications in myxedema coma, the IV route is recommended until the patient is alert and able to tolerate oral intake, and then maintenance T₄ alone is continued.75,83

General Supportive Measures

The management of hyponatremia in myxedema coma requires water restriction, but in the face of the volume depletion and hypotension seen in myxedema coma, normal saline solutions should be used. If hyponatremia is severe (<120 mEq/L), hypertonic saline in 50- to 100-mL boluses should be considered.75,83-85

Hydrocortisone should be administered to all patients in myxedema coma. A small proportion of these patients may have central hypothyroidism where concomitant adrenocorticotropic hormone (ACTH) deficiency may be present. Another subset may have autoimmune destruction of both the thyroid and adrenal glands (Schmidt syndrome). Most patients are presumed to suffer from relative adrenal insufficiency unmasked by stress and the enhanced clearance of cortisol. Hydrocortisone is given IV, 50 to 100 mg, every 6 to 8 hours for several days.75

Hyponatremia is treated with passive rewarming, using regular blankets and prevention of further heat loss. Heating blankets could be employed, but there is risk that the resulting vasodilatation will lead to a fall in peripheral vascular resistance and hypotension. As in accidental hypothermia, excessive mechanical stimulation should be avoided due to risk of precipitating arrhythmias.

Identification and Treatment of Precipitating Illness

Concomitant with the previous treatment measures, a precipitating illness for myxedema coma should be sought and treated aggressively with special attention paid to a potential infectious cause, which accounts for about one third of cases.89,90

Without thyroid hormone replacement and a vigorous approach, the mortality rate from myxedema coma exceeds 80%; but with the comprehensive approach described and monitoring in the intensive care unit, the mortality rate falls to 20% or less. Factors that predict a poor outcome in myxedema coma include advanced age, a body temperature of less than 90°F or hypothermia refractory to treatment, hypotension, pulse less than 44 beats per minute, and sepsis.91-93

Adrenal Insufficiency

Perspective

Adrenal insufficiency in its chronic form is an uncommon disease with nonspecific symptoms that include fatigue, weakness, weight loss, depression, and nonspecific gastrointestinal symptoms. This presentation is difficult to diagnose on a single encounter, yet recognition is critical as an acute superimposed stress can lead to vascular collapse and death. The acute development of severe adrenal insufficiency de novo can also occur and be life-threatening. Both the acute and chronic forms of adrenal insufficiency can be primary, due to adrenal gland destruction, or secondary, caused by pituitary gland failure to produce ACTH. Recognition of acute adrenal insufficiency and prompt administration of hydrocortisone is critical to patient survival.94-97

Principles of Disease

The adrenal cortex produces cortisol, aldosterone, and androgens, and the adrenal medulla produces catecholamines. Primary adrenal failure leads to a deficit of cortisol and aldosterone only, but catecholamine and androgen production continues from other sites. Secondary adrenal failure is related to decreased production of ACTH from the pituitary gland and as a result, only cortisol deficiency develops, as aldosterone is regulated by the rennin-angiotensin system. Cortisol has numerous actions that include facilitating gluconeogenesis and lipolysis, inhibiting insulin secretion, anti-inflammatory actions, immune-modulating effects, augmenting vascular reactivity to vasoconstrictors, promoting catecholamine synthesis, and retarding bone growth.94,96-97 Aldosterone acts primarily at the distal nephron where it promotes the reabsorption of sodium and the excretion of potassium and hydrogen. A deficiency of cortisol alone may lead to blood pressure lower-
Etiology

Primary failure of the adrenal gland is referred to as Addison’s disease, and the majority of such cases in the Western world are due to autoimmune adrenalitis, with about half of these being isolated deficiencies and the other half associated with a polyglandular autoimmune syndrome (PGA). There are two variants of the PGA: PGA type I is a rare autosomal recessive condition consisting of Addison’s disease, hyperparathyroidism, chronic mucocutaneous candidiasis, and vitiligo. PGA type II (Schmidt’s syndrome), the predominant form, includes primarily Addison’s disease and hypothyroidism, as well as diabetes and hypogonadism94-97 (Box 126-12).

 Destruction of the adrenal glands by tuberculosis is the most common cause of Addison’s disease worldwide, but is rare now in the United States except when associated with AIDS. Other disseminated infections such as cryptococcosis, histoplasmosis, blastomycosis, CMV, toxoplasmosis, and lung disease from Mycobacterium avium-intercellulare, and Pneumocystis may result in adrenalitis and Addison’s disease, but these too are seen almost exclusively in the setting of HIV infection. Infiltration with Kaposi’s sarcoma and direct involvement by HIV alone may lead to adrenal insufficiency, and overall, about 20% of HIV patients who are critically ill have laboratory evidence of cortisol deficiency.98

Adrenal metastases, most commonly from lung and breast cancer, are often found at autopsy, but symptomatic adrenal insufficiency is seen in only about 4% of these patients, probably because over 90% of both adrenals must be destroyed before function is affected. Infiltration of the adrenals by non-malignant processes, such as sarcoid, amyloid, and hemochromatosis may also lead to Addison’s disease.96,97

Drug therapy may precipitate or unmask adrenal insufficiency. The most noteworthy cause is etomidate, an imidazole agent used in the induction and maintenance of anesthesia. Etomidate blocks cortisol synthesis by inhibiting the 11β-hydroxylase enzyme. Etomidate infusions in an intensive care setting have been associated with acute adrenal insufficiency and are not recommended, but bolus administration for rapid sequence intubation appears safe, yet rare cases of crisis have been described.99,100 Adrenal inhibition subsequent to a single etomidate bolus can be demonstrated in 80% of patients in the first 12 hours, and about one half at the 24-hour mark, followed by rapid resolution by 48 hours.101 Trends toward hypotension and pressor use have been demonstrated in trauma patients admitted to an intensive care unit who have received rapid sequence intubation with etomidate, but a cause-and-effect relationship is difficult to assess. Other drugs that may aggravate adrenal insufficiency include ketoconazole (inhibits cortisol synthesis), rifampicin (increases cortisol catabolism), and megastrol acetate (stimulates the glucocorticoid receptor and suppresses ACTH).102

The presentation of hypoaldosteronism in childhood often suggests an inherited disorder such as PGA syndromes, adrenoleukodystrophy, adrenal hypoplasia, or ACTH unresponsiveness.96,97

The development of bilateral hemorrhagic infarction of previously normal adrenal glands can result in acute adrenal insufficiency, carrying a very high mortality rate. Meningococcal sepsis (Waterhouse-Fridrichsen syndrome) is classically described, but infections with Pseudomonas, Escherichia coli, group A Streptococcus, Pneumococcus, and Staphylococcus can result in a similar syndrome.103

Adrenal hemorrhage or infarction from coagulopathies can also result in acute adrenal insufficiency if 90% of both glands are involved. Warfarin or heparin anticoagulation in excess or during severe stress can result in hemorrhage that leads to acute crisis.104 Venous infarction of the adrenals resulting in addisonian crisis has been described in the antiphospholipid antibody syndrome, and in one series it was the presenting manifestation of the disease in 36% of patients.105 Adrenal hemorrhage has also been described in blunt thoracoabdominal trauma, but although associated liver, spleen, and kidney injuries are common, adrenal insufficiency is rare.106

Acute and chronic hypoaldosteronism may also result from ACTH deficiency, in which exogenous glucocorticoid therapy is the most common cause. Reduced responsiveness and possible atrophy of the adrenal gland can be anticipated whenever supraphysiologic doses of a glucocorticoid (hydrocortisone .30 mg, prednisone 7.5 mg, or dexamethasone 0.75 mg daily) are taken for more than 3 weeks, but as little as 5 days is required if the daily dose exceeds the equivalent of 20 mg of prednisone.94,96,97 Inhibition of ACTH secretion depends not only on the dose and duration of therapy but also on the frequency and timing of the dose, such that more than once per day and any evening dose have a much greater suppressive

effect on pituitary ACTH, even if by the inhalational route.107

Other causes of secondary adrenal insufficiency result from direct destruction of the pituitary gland. Chronic hypopituitarism can result from pituitary adenomas or metastatic involvement, surgical hypophysectomy or pituitary irradiation, and granulomatous disease of the pituitary (sarcoid, tuberculosis, eosinophilic granuloma).66

Acute onset of secondary adrenal insufficiency can result from hemorrhage into a pituitary adenoma, referred to as pituitary apoplexy. Ischemic necrosis of the pituitary associated with hypotension, most commonly in the postpartum period (Sheehan’s syndrome), can result in either acute or chronic hypoadrenalism and hypopituitarism.108

Traumatic brain injury is an increasingly recognized cause of central hypoadrenalism. In a compilation of 710 patients, the majority of whom presented with a Glasgow Coma Score of 3 to 13, 13% developed ACTH deficiency, many were evident in the initial hospitalization, but some presented up to 6 months after injury. Similar percentages were seen for growth hormone and gonadotropin deficiencies.109,110

Functional adrenal insufficiency, another central cause of hypoadrenalism, occurs in critically ill patients who have an inability to mount an adequate ACTH and cortisol response to sepsis or overwhelming stress, leading to increased mortality during the acute illness. Looking specifically at septic shock, more than 50% of patients have evidence of this relative adrenal insufficiency.111-114

### Symptoms and Signs

The presentation of Addison’s disease and other causes of chronic primary adrenal gland failure is often vague and nonspecific, with the insidious onset of fatigue, generalized weakness, and weight loss. Gastrointestinal symptoms are common with nausea, intermittent vomiting, abdominal pain, and diarrhea or constipation.115 Low-grade fever, arthralgias, and muscle cramps suggest a persistent flulike syndrome. Salt craving, sometimes with massive salt ingestion, and postural dizziness or syncope result from concomitant mineralocorticoid deficiency. Psychiatric symptoms occur early in the disease and may predate other symptoms. The most common presentations include depression, manifested by apathy and lack of initiative, memory impairment that can progress to confusion and delirium, a dementia-like picture, and psychosis.94-97

Adrenal insufficiency due to ACTH deficiency may present with similar symptoms, but salt craving and postural hypotension are absent because the renin-aldosterone axis remains intact. Symptoms often relate more to deficiency of pituitary hormones other than ACTH, specifically follicle-stimulating hormone/luteinizing hormone, resulting in loss of libido, infertility, amenorrhea, and TSH with cold intolerance and weight gain.66,94,96

In most cases Addison’s disease is not recognized until an acute intercurrent illness precipitates a crisis, but some clinical clues may alert the clinician to the diagnosis. The systolic blood pressure is usually below 110 mm Hg, and postural changes may be found. Hyperpigmentation of sun-exposed areas, palmar creases, nipples, axillae, recent scars, and all mucous membranes is typically seen in Addison’s disease, due to compensatory elevation of ACTH, which in turn stimulates melanocyte receptors to produce melanin. In women, loss of adrenal androgen can lead to thinning of pubic and axillary hair. Patients with secondary adrenal insufficiency lack hyperpigmentation and hypotension, and thus the condition is more difficult to identify. Vitiligo may be seen in 10 to 20% of patients with Addison’s disease associated with polyglandular autoimmune syndrome I. Auricular cartilage calcification is an unexplained phenomenon seen in men with either chronic primary or secondary adrenal insufficiency.116,117

Most adrenal crises occur in the setting of chronic adrenal insufficiency in which almost any acute intercurrent illness or stress overwhelms the patients limited cortisol reserve. Less common, but a more fulminating presentation, is acute adrenal or pituitary hemorrhage or infarction.64,103,108

The presentation of acute adrenal insufficiency can vary from a picture suggesting acute gastroenteritis with nausea, vomiting, fever, and dehydration to sudden vascular collapse and death. The cardinal feature of adrenal crisis is hypotension or shock out of proportion to the severity of the current illness. Despite aggressive fluid resuscitation, the blood pressure typically shows little response and is often refractory to pressors.94-96

Abdominal pain may be a presenting symptom, mimicking an acute abdomen, this picture being particularly dramatic with acute adrenal hemorrhage or infarction. Hypotension accompanying sudden severe headache and visual field cuts suggests acute pituitary apoplexy.

### Diagnostic Strategies

The diagnostic approach to adrenal insufficiency depends on whether you are screening for a chronic condition or evaluating an acutely ill or critical patient, but in all circumstances the serum cortisol measurement is the mainstay. Serum cortisol has a diurnal variation, peaking between 6 and 8 AM, and reaching a nadir in the late evening and during early sleep. Screening the patient who is not acutely ill starts with an am cortisol

Hypoadrenalism is seen in about 90% of patients with chronic primary adrenal insufficiency. It is usually of mild to moderate severity, seldom below 120 mEq/L. Adrenal gland failure leads to aldosterone deficiency, which results in sodium loss. In addition, cortisol deficiency leads to increased antidiuretic hormone secretion and excess water reabsorption. Although aldosterone is not deficient in secondary adrenal insufficiency, increased antidiuretic hormone secretion alone results in hyponatremia in about 50% of patients and it may be severe. In hypoadrenalism of either cause, the administration of hydrocortisone suppresses antidiuretic hormone production and can correct hyponatremia.

Due to aldosterone deficiency, hyperkalemia is seen in about two thirds of patients with primary adrenal insufficiency, but it is absent in secondary causes where aldosterone production is not affected. Serum potassium elevation is usually mild in Addison’s disease and rarely exceeds 7 mEq/L. A mild hyperchloremic metabolic acidosis usually accompanies the elevated potassium due to impaired exchange of sodium with hydrogen and potassium when aldosterone is deficient.

Older reviews describe fasting hypoglycemia in more than two thirds of patients with Addison’s disease, whereas more recent literature suggests that hypoglycemia is more pronounced in secondary adrenal insufficiency and is often the presenting manifestation. Inhibition of gluconeogenesis resulting from cortisol deficiency, as well as reduced calorie intake and depletion of glycogen stores, makes adrenal insufficiency a set-up for hypoglycemia. Deficiency of growth hormone and ACTH in hypopituitarism further increases the propensity to and severity of hypoglycemia. Patients with type I diabetes and adrenal insufficiency often present with unexplained recurrent hypoglycemic reactions.

Other laboratory abnormalities seen in adrenal insufficiency include hypercalcemia in about 6%, elevated BUN and creatinine in 55%, anemia in 40%, and eosinophilia in 17%. Evaluation of the etiology of hypoadrenalism is usually beyond the scope of the emergency physician, but abdominal computed tomography may reveal adrenal hemorrhage, infarction, or metastatic disease, while computed tomography of the brain may demonstrate pituitary hemorrhage, tumor, or empty sella.

**Differential Diagnosis**

Chronic adrenal insufficiency may be marked by wasting suggestive of anorexia nervosa or occult carcinoma. Generalized weakness, fatigue, and myalgias resemble chronic fatigue syndrome, polymyalgia rheumatic, myopathy, hypothyroidism, or flu syndromes.

Acute adrenal crisis with refractory hypotension often leads to a search for sepsis, gastrointestinal bleeding, myocardial ischemia, or anaphylaxis. Abdominal pain in crisis may mimic an acute abdomen especially if precipitated by adrenal hemorrhage. The headache and visual field cuts in pituitary apoplexy may resemble a hemorrhagic stroke.

Steroid withdrawal syndrome should be distinguished from adrenal insufficiency as both can occur with the cessation of chronic glucocorticoid therapy. Steroid withdrawal syndrome is characterized by symptoms that resemble chronic adrenal insufficiency, including weakness, malaise, fatigue, nausea, dizziness, and arthralgias. Patients with steroid withdrawal syndrome, however, are not predisposed to adrenal crisis as their hypothalamic-pituitary-adrenal axis is intact by ACTH stimulation testing.

**Management**

Acute adrenal insufficiency and relative adrenal insufficiency of sepsis and critical illness are life-threatening conditions in which aggressive fluid resuscitation, hydrocortisone replacement, and treatment of any precipitating illness are the main-
Hydrocortisone is the glucocorticoid of choice as it has intrinsic mineralocorticoid effects. In a nonacute setting, dexamethasone should not be used in this acute setting, as it has no mineralocorticoid effects. In a nonacute setting, dexamethasone should not be used in this acute setting, as it has no mineralocorticoid effects. Dexamethasone should not be withheld awaiting laboratory confirmation. Hydrocortisone, 20 mg, is given prior to the procedure.96

**Hyponatremia is high. Bicarbonate is not required for the correction of acidosis and hyperkalemia, as rapid correction is generally seen with saline and hydrocortisone administration (Box 126-14).**

Blood should be drawn for random serum cortisol and ACTH, as well as electrolytes, but hydrocortisone treatment should not be withheld awaiting laboratory confirmation. Hydrocortisone is the glucocorticoid of choice as it has intrinsic mineralocorticoid properties, which obviates the need to administer a mineralocorticoid separately. Dexamethasone should not be used in this acute setting, as it has no mineralocorticoid effects. In a nonacute setting, dexamethasone is often suggested for glucocorticoid replacement while an ACTH stimulation test is being performed since it does not interfere with cortisol measurements. In a critical patient with possible adrenal insufficiency, an ACTH stimulation test is not recommended due to inherent delays.95,112,113

Approximately 200 to 300 mg per day of hydrocortisone is considered a physiologic stress dosage, such that dosage recommendations range from 50 to 100 mg IV every 6 to 8 hours. Another option is to administer a 50- to 100-mg bolus of hydrocortisone, followed by an infusion of 20 mg per hour.

If the diagnosis of adrenal insufficiency is correct, these measures will improve the blood pressure and clinical picture over 4 to 6 hours. A careful search for a precipitating cause, especially infections, should have been completed by now and empirical antibiotic therapy often started. The rate of saline infusion and the dose of IV steroids can often be tapered after 24 hours. By the third or fourth day, conversion to oral hydrocortisone is feasible, usually at twice the maintenance dose (40 mg AM, 20 mg PM) initially, then to the standard replace-

### BOX 126-14  TREATMENT OF HYPOADRENALISM

| Maintenance | Hydrocortisone 20 mg AM, 10 mg PM  
| Maintenance during Minor Illness | Hydrocortisone 40 mg AM, 20 mg PM  
| Fludrocortisone 100 µg/day  
| Fludrocortisone 100 µg daily  
| Coverage during Procedural Stress | Hydrocortisone 100 mg IV (one time only)  
| Adrenal Crisis or Relative Adrenal Insufficiency of Critical Illness | Hydrocortisone 50–100 mg IV every 6 hr  
| OR | Hydrocortisone 50–100 mg IV followed by an infusion, 20 mg/hr  
| 0.9 NS 2–3 L over the first few hours  
| Switch to D5 NS if hypoglycemia  
| Treat precipitating illness  

D5, NS, 5% dextrose in normal saline.

...stays of treatment. IV access should be established with two large-bore IVs and 2 to 3 L of 0.9% saline should be infused over the first few hours, monitoring for signs of fluid overload and blood pressure response. A bedside glucose should be determined due to the frequent incidence of hypoglycemia and 5% dextrose in normal saline substituted if indicated. Hypotonic fluids should be avoided as the frequency of hyponatremia is high. Bicarbonate is not required for the correction of acidosis and hyperkalemia, as rapid correction is generally seen with saline and hydrocortisone administration (Box 126-14).  

Chronic replacement therapy in patients with established adrenal insufficiency consists of hydrocortisone, 20 mg on arising and 10 mg at 6 PM, as well as fludrocortisones, 100 µg per day. During minor to moderate febrile illness or stress, the patient should be advised to increase the glucocorticoid dose two- to threefold for the few days of illness, but the fludrocortisone dose is not changed. For moderately stressful procedures like endoscopy or angiography, a single 100-mg IV dose of hydrocortisone is given prior to the procedure.96

### KEY CONCEPTS

- **Thyroid storm** is a life-threatening decompensation of severe hyperthyroidism precipitated by an intercurrent illness, typically sepsis. The hallmarks of thyroid storm include hyperthermia, exaggerated tachycardia, altered mental status, and gastrointestinal symptoms. Therapy of thyroid storm includes actions to reduce production of thyroid hormone, to inhibit thyroid hormone release, to block peripheral conversion of T4 to T3, to initiate beta-adrenergic blockade, to institute general supportive measures, and to identify and treat the precipitating event.

- **Myxedema coma** is a life-threatening deterioration of severe chronic hypothyroidism precipitated by an acute intercurrent illness. The prototypical case is an elderly woman in the winter who presents with marked hypothermia, altered mental status, respiratory failure, and hypotension. The management of myxedema coma requires immediate attention to airway management, fluid resuscitation, thyroid hormone replacement, general supportive measures, and treatment of the precipitating illness.

- **Hallmarks of chronic adrenal insufficiency** include generalized weakness, malaise, fatigue, gastrointestinal symptoms, weight loss, blood pressure less than 110/70 mm Hg, and hyponatremia. Primary autoimmune adrenal failure is the more common cause and is distinguished by the presence of hyperpigmentation, hyperkalemia, and more severe orthostasis. Hypopituitarism resulting in secondary adrenal insufficiency is distinguished by more severe hypoglycemia and the lack of the classic features seen in primary disease.

- **Hypotension refractory to fluid resuscitation** may be the only clue to the diagnosis of adrenal crisis or relative adrenal insufficiency of critical illness. In this setting, a random serum cortisol level should be obtained and IV hydrocortisone administered before confirmation is obtained.

DIPHTHERIA

Perspective

Background

References to the disease now known as diphtheria date back to ancient Syria and Egypt. In the fifth century BC, Hippocrates provided the first clinical description of this disease characterized by sore throat, membrane formation, and death through suffocation. Epidemics of “throat distemper” were described throughout the 16th, 18th, and 19th centuries. In 1821 French physician Pierre Bretonneau named the condition “diphtherite,” from the Greek word for “leather,” to describe the characteristic pharyngeal membrane. Klebs observed the Corynebacterium diphtheriae microorganism on smears obtained from pharyngeal membranes in 1883, and 1 year later Löffler isolated Corynebacterium organisms in pure cultures. Löffler subsequently demonstrated that diphtheria was a localized infection and postulated that its systemic effects were caused by an elaborated toxin. In 1888 Roux and Yersin demonstrated that bacteria-free filtrates of diphtheria culture were able to kill guinea pigs.

In 1890 von Behring and Kitasato first demonstrated diphtheria immunization using a heat- and formalin-treated toxin to make toxoid. One year later they administered the first dose of antitoxin to a human with diphtheria. Schick developed the skin test for diphtheria immunity in 1913. During the 1930s and 1940s, toxoid immunization was routinely used. In the 1950s Freeman found that only bacteria infected with the B phage produced toxin. Subsequent studies elucidated the toxin genome and the mechanism of toxin activity at the cellular level.

Epidemiology

Humans are the only known reservoir for C. diphtheriae. Spread is primarily by person-to-person contact through respiratory droplets or by direct contact with skin lesion exudates. Transmission is associated with crowded living conditions. Individuals may spread the disease when they are actively ill, in the convalescent stage after acute illness, or as asymptomatic carriers. Fomites and foods have occasionally been implicated but do not represent a major route of transmission.

Between 1991 and 1996 the first large-scale epidemic of diphtheria in an industrialized country in three decades occurred in the newly independent states of the former Soviet Union. During the peak of the epidemic more than 98,000 cases and 3400 deaths were reported. Several factors contributed to this outbreak, including (1) decreased childhood immunity due to vaccine supply interruption and administration of adult-formulation tetanus-diphtheria toxoids (Td) to children, (2) increased adult susceptibility due to waning immunity, (3) poor socioeconomic conditions and increased population movement, and (4) resurgence of more toxigenic strains of diphtheria.

Immunization against diphtheria is highly effective. Before widespread immunization programs in the United States, the incidence of diphtheria was in excess of 100 cases per 100,000 population, and the disease predominantly affected children. During this time, 80% of people acquired natural immunity to diphtheria by age 15, and recurrent exposure to toxigenic strains of the bacteria acted as boosters. Because childhood immunization nearly eliminates these toxigenic strains in a population, adult immunity wanes. Thus, more adults in industrialized nations are susceptible to diphtheria. By 1980 the Centers for Disease Control and Prevention (CDC) reported 0 to 5 cases per year nationwide. Currently, sporadic cases occur primarily in adults, many of whom are not adequately immunized. Three urban outbreaks of predominantly cutaneous diphtheria occurred in Seattle between 1972 and 1982 among a population of urban alcohol abusers. Outbreaks are associated with poor hygiene, crowding, underlying skin disease, contaminated fomites, pyoderma, and the appearance of new C. diphtheriae strains. Even in industrialized nations in which childhood vaccination rates are high, more than 50% of adults older than 40 lack protective antibodies. The ease of international travel and the epidemic in eastern Europe in the 1990s underscore the importance of aggressively continuing childhood immunizations and reimmunization of adults.

Principles of Disease

Etiology

Diphtheria is caused by C. diphtheriae, an unencapsulated, gram-positive bacillus named for its shape (“korynee” for club) and for its characteristic clinical presentation (“diphtheria” for “leather hide,” referring to the appearance of the pharyngeal membrane). When viewed on stained smears, the bacteria look like Chinese characters.

Infection by C. diphtheriae occurs at various sites of the respiratory tract or the skin. Respiratory diphtheria includes faucial (pharyngeal or tonsillar), nasal, and laryngeal (tracheobronchial) types, named for the primary location of infection.
Cutaneous diphtheria may occur as a primary skin infection or as a secondary infection of a preexisting wound.

Pathophysiology

The *C. diphtheriae* bacterium produces an exotoxin that contributes to formation of the diphtheritic membrane and is responsible for the systemic effects of infection. The exotoxin is a 62,000-dalton polypeptide produced by bacterial strains lysogenized by the corynebacterial *B. tox*. The exotoxin inhibits cellular protein synthesis. Circulating exotoxin most profoundly affects the nervous system, heart, and kidneys. The degree of local and systemic toxicity depends on the location and extent of membrane formation. Pharyngeal diphtheria generally has the greatest toxicity and cutaneous diphtheria the least.

The diphtheritic membrane forms as a result of necrosis caused by the local effects of the exotoxin. The membrane is composed of leukocytes, erythrocytes, fibrin, epithelial cells, and bacteria. Initially, the pharynx appears erythematous, but as necrosis occurs, grayish-white patches appear and eventually coalesce. This membrane adheres to the underlying tissue, and bleeding occurs if removal is attempted.

Systemic effects of diphtheria infection are caused by the circulating exotoxin’s action primarily on the cardiovascular and nervous systems. The exotoxin’s disruption of cellular protein synthesis produces a peripheral neuropathy manifested by muscle weakness. About 20% of all patients with symptomatic respiratory infection have polyneuritis, but 75% of patients with severe disease develop some form of neuropathy. The muscles of the palate are usually the first to become paralyzed. Less commonly, other cranial nerves, peripheral nerves, and the spinal cord may be affected. Degenerative lesions develop in the dorsal root and ventral horn ganglia of the spinal cord and in cranial nerve nuclei. Cortical cells are spared. Proximal muscle groups are affected first. In severe cases, paralysis may develop in the first few days of illness. Generally the paralysis does not last more than 10 days, and complete recovery over a longer period of time is the rule.

The extent of cardiac complications correlates with the degree of local infection and membrane formation. Signs of myocardial dysfunction usually appear 1 to 2 weeks after the onset of illness. In more severe cases, cardiac symptoms arise earlier in the course of the illness. The exotoxin directly damages myocardial cells, producing myocarditis. Electrocardiographic (ECG) changes suggestive of myocarditis occur in up to two thirds of patients, but clinical manifestations of myocarditis are less common (10–25%).

Clinical Features

Symptoms and Signs

The average incubation period of respiratory tract diphtheria is 2 to 4 days but may range from 1 to 8 days. Signs and symptoms are often indistinguishable from those of other upper respiratory tract infections. In a series of 676 patients, fever and sore throat were the most frequent presenting complaints (79% and 69%, respectively). Weakness (42%), dysphagia (35%), headache (20%), change of voice (15%), and loss of appetite (10%) were also common. Cough, shortness of breath, nasal discharge, and neck edema occurred in less than 10% of patients. Fever, although common, is usually low grade. Cervical adenopathy is present in approximately one third of patients, and a diphtheritic membrane is observed in more than half of all patients. Of note, however, one report indicated that shortness of breath and neck edema were present in approximately 40% of patients who died of the disease.

In patients with faucial diphtheria, the extent of the membrane usually parallels the clinical toxicity. If the membrane is limited to the tonsils, the disease may be mild; if the membrane covers the entire pharynx, the onset of illness is usually abrupt and the disease severe. Swelling of the cervical lymph nodes and infiltration of tissues of the neck may be so extensive that the patient has a “bull-neck” appearance. Patients with this form of “malignant diphtheria” usually have high fever, severe muscle weakness, vomiting, diarrhea, restlessness, and delirium. Death occurs from respiratory tract obstruction or cardiac failure from myocarditis. Nasal diphtheria arises with a unilateral or bilateral serous or serosanguineous discharge from the nose. A diphtheritic membrane may be visible. These patients do not usually develop constitutional symptoms. Treatment is important to prevent a persistent carrier state. Laryngeal (tracheobronchial) diphtheria may begin in the larynx or spread downward from a more cephalad primary site. Respiratory tract edema with subsequent upper airway obstruction may develop.

Patients with cutaneous diphtheria generally do not display systemic toxicity. The skin characteristically has an ulcer with a grayish membrane. Wounds from which *C. diphtheriae* is cultured are clinically indistinguishable from other chronic skin conditions.

Complications

The most serious complications of diphtheria are airway obstruction (resulting from membrane formation and edema), congestive heart failure, cardiac conduction disturbances, and muscle paralysis. Mortality in two large series ranged from 2.3 to 3% overall but was up to 7% in patients with myocarditis and 25.7% in patients with the malignant form of the disease (with neck swelling). Unimmunized and underimmunized children requiring intensive care may have higher mortality rates (78.1%) from myocarditis and often develop renal failure. Although systemic infection is rare, endocarditis, mycotic aneurysms, osteomyelitis, and septic arthritis have all been described in immunocompromised hosts.

Diagnostic Strategies

When *C. diphtheriae* is suggested, the laboratory should be notified because routine cultures do not identify the organism. Throat or nasopharyngeal swabs should be obtained for respiratory diphtheria, and, if present, membranous material should be examined. For cutaneous infections, samples should be obtained from skin lesions. Specimens should be collected before antibiotic therapy is initiated and should be transported to the laboratory immediately for rapid inoculation onto tellurite (Tinsdale’s) or Löffler’s selective culture medium. Immunofluorescent staining of a 4-hour culture may provide a rapid diagnosis, but direct staining is frequently unreliable. Definitive identification is made by using a combination of colony morphology, microscopic appearance, and fermentation reactions. *C. diphtheriae* isolates should be tested for the production of toxin. The Elek immunoprecipitation test for toxin A is technically demanding and subject to misinterpretation by inexperienced users. Polymerase chain reaction (PCR), which is more reliable but not as readily available, can be used to detect the diphtheria toxin structural gene. A positive culture for group A beta-hemolytic streptococcus does not exclude diphtheria as a pathogen, as up to 30% of patients with
Differential Diagnosis of Respiratory Diphtheria

Streptococcal or viral pharyngitis
Tonsillitis
Vincent’s angina
Acute epiglottitis
Mononucleosis
Laryngitis
Bronchitis
Tracheitis
Monilial infection (thrush)
Rhinitis

Diphtheria test positive for streptococcal coinfection or carrier state.

Several laboratory abnormalities such as leukocytosis, mild thrombocytopenia, and proteinuria are common but are neither sensitive nor specific for diphtheria. ECG changes are nonspecific and include ST-T wave changes, varying degrees of atrioventricular block, and dysrhythmias. An ECG may be normal even in the presence of myocarditis. Cardiac enzymes may detect myocarditis, and serum troponin levels correlate with the severity of myocarditis.10

Differential Considerations

In the absence of a diphtheritic membrane, it may be difficult to differentiate respiratory diphtheria from many other respiratory conditions, especially in the early phase of infection (Box 127-1). Generally, the diphtheritic membrane is darker, grayer, more fibrous, and more firmly attached to the underlying tissues than in other conditions that have a membrane-like appearance. Vincent’s angina frequently involves the gingivae, which are unaffected in diphtheria. Acute bacterial epiglottitis generally has a much more rapid onset than diphtheria, and indirect laryngoscopy reveals an erythematous, edematous epiglottis without membrane formation.1

Cutaneous diphtheria is difficult to differentiate from other acute and chronic ulcerative skin lesions. C. diphtheriae can secondarily infect any of these lesions, especially in high-risk patients such as alcoholic, socioeconomically disadvantaged, and immunized or underimmunized people.

Management

Patients with clinical evidence of diphtheria should be placed in respiratory isolation and treated presumptively for C. diphtheriae. The goals of therapy are to protect the airway, limit the effects of already produced toxin, and eliminate future toxin production by terminating the growth of C. diphtheriae. Although the likelihood of a patient in the United States developing airway obstruction from diphtheria is remote, the management is identical to that for other forms of airway obstruction. Bronchodilators may be useful in symptomatic patients.10 Patients may be dehydrated from fever and decreased oral intake related to dysphagia or neurologic impairment. Fluid resuscitation should be undertaken cautiously as the toxin’s effect on the myocardium may result in congestive heart failure.

Equine serum diphtheria antitoxin (DAT) should be administered promptly after the clinical diagnosis of respiratory diphtheria is made. DAT is not licensed by the Food and Drug Administration (FDA) for use in the United States. The CDC is authorized to distribute DAT to physicians as an investigational new drug. DAT can be obtained by contacting the CDC Emergency Operations Center at 770-488-7100. The diphtheria duty officer can also be contacted at 404-639-3158 during duty hours.11 The size and location of the membrane, duration of illness, and the patient’s overall degree of toxicity determine the dosage of antitoxin. The Committee on Infectious Diseases of the American Academy of Pediatrics (AAP) recommends 20,000 to 40,000 units for pharyngeal or laryngeal involvement of 48 hours’ duration, 40,000 to 60,000 units for nasopharyngeal lesions, and 80,000 to 120,000 units for extensive disease of 3 or more days’ duration or for diffuse swelling of the neck.10,11 After conjunctival or intradermal sensitivity skin testing, the antitoxin is administered intravenously (IV). If the patient exhibits sensitivity to the antitoxin, desensitization should be performed. Active immunization against diphtheria should also be initiated because clinical infection does not necessarily confer immunity.10

Antibiotics are beneficial in preventing growth and spread of the organism but are no substitute for antitoxin. Erythromycin, 40 to 50 mg/kg/day (up to 2 g) IV or orally in divided doses, intramuscular (IM) aqueous crystalline penicillin (100,000–150,000 units/kg/day in four divided doses), and procaine penicillin (25,000–50,000 units/kg/day in two divided doses) for 14 days given IM are acceptable alternatives.10,12 Treatment failures are more common with penicillin than with erythromycin. The newer generation macrolides (azithromycin and clarithromycin) have activity similar to that of erythromycin in vitro and may result in better compliance. These agents have not yet been adequately tested in clinical disease. An equivalent daily oral therapy may be substituted when the patient is able to swallow. Three negative cultures should be documented after treatment.12

Myocarditis and neuritis are treated with supportive care and careful monitoring. Patients with ECG changes of myocarditis have three to four times the mortality rate of those with normal ECGs. The mortality rate for patients with left bundle branch block and atrioventricular block is 60 to 90%, and serial tracings are recommended. No data support the use of steroids.1,10

Cutaneous lesions should be débrided of necrotic tissue and cleansed vigorously. A course of antibiotics is recommended, but the administration of antitoxin for cutaneous lesions is of questionable value. Some experts recommend 20,000 to 40,000 units of antitoxin, but few data support its use in this setting.1,12

Carriers of C. diphtheriae should receive oral penicillin G or erythromycin for 7 days or IM benzathine penicillin (600,000 units for those less than 30 kg and 1,200,000 units for those over 30 kg). Active immunization should also be provided to unimmunized and partially immunized carriers. After 2 weeks of therapy is completed, cultures should be obtained; if cultures are positive, erythromycin therapy should be given for 10 additional days.12

Individuals who have been in close contact with infected patients should have culture specimens taken, and the patient should be kept under surveillance for 7 days. Previously immunized close contacts should receive a booster of diphtheria toxoid if the last booster was more than 5 years earlier. The vaccine should be diphtheria, tetanus, and pertussis (DTP), diphtheria-tetanus (DT), or tetanus-diphtheria with a lower dose of diphtheria toxoid (Td) as appropriate for age according to the recommended immunization schedule. Close contacts who are not immunized or whose immunization status is unknown should receive the same antimicrobial therapy as carriers (as previously described), have culture specimens taken before and after therapy, and have active immunization initiated. Close contacts who cannot be kept under surveillance should receive benzathine penicillin IM to ensure com-
Disposion

All patients with possible pharyngeal diphtheria should be isolated and admitted. A monitored setting is recommended for the early detection of arrhythmias. A cardiologist should be consulted for patients with evidence of myocarditis. The CDC should be contacted for all suggested or proven cases of diphtheria.

PERTUSSIS

Pertussis is an acute respiratory disease that was first described in 1578 when an epidemic swept through Paris. The name “pertussis” was first used by Sydenham in 1670 when he described the illness in infants. Pertussis literally means “violent cough,” which is the hallmark of the disease. In China it is known as “the cough of 100 days.” It is also called whooping cough because the severe episodes of coughing are followed by forceful inspiration, which creates the characteristic whooping sound. The causative organism was identified in 1906 by Bordet and Gengou.13 In the prevaccination era, pertussis was a major cause of mortality among infants and children in the United States. A vaccine was developed in the 1940s, but pertussis still remains a significant cause of morbidity and mortality in the United States and worldwide.

Epidemiology

Pertussis is a localized respiratory illness transmitted by aerosolized droplets. It is highly contagious, with attack rates greater than 50% in adults exposed more than 12 years after completion of a vaccination series, and up to 100% in susceptible individuals with a household exposure.13 The average incubation period is 7 to 10 days but may range from less than 1 week to 3 weeks. Neither vaccination nor prior infection confers lifelong immunity.

Pertussis remains prevalent worldwide. In the United States, annual pertussis rates declined sharply after the introduction of the vaccine and reached a nadir of 1010 cases in 1976. Since then, there has been a steady increase in the incidence of pertussis, with 11,647 cases reported in 2003 (Fig. 127-1A and B).14 Waning immunity in the adult population and increased reporting of adult cases may be contributing factors. A 1991 report found evidence of a causal relationship between the
vaccine and acute encephalopathy. Although there appears to be no causal relationship between the vaccine and long-term neurologic complication, the report resulted in a decline in the use of the whole-cell pertussis vaccine. The acellular pertussis vaccine has been approved in the United States since 1991 for persons older than 15 months and since 1996 for infants.

Although pertussis can occur at any age, it is predominantly a pediatric and adolescent illness. The age-specific attack rates are highest in children younger than 1 year who have not yet received the entire vaccine series. There appears to be a seasonal variation; 50% of cases in the United States occur from June through September.

### Principles of Disease

#### Etiology

Pertussis is caused by organisms of the *Bordetella* genus, which are small, motile, gram-negative cocccobacilli that occur singly or in pairs. *Bordetella pertussis* and *Bordetella parapertussis* are responsible for disease in humans. The organisms are fastidious and require nicotinamide and an optimal temperature of 35° C to 37° C to grow. *Bordetella bronchiseptica*, a flagellated, motile organism, causes illness in animals, including kennel cough, and may rarely cause respiratory infection in immunocompromised humans. 

#### Pathophysiology

The *Bordetella* organism adheres preferentially to ciliated respiratory epithelial cells. *B. pertussis* does not invade beyond the submucosal layer in the respiratory tract and is almost never recovered in the bloodstream. The organism elaborates several toxins that act locally and systemically. These toxins include pertussis toxin, dermonecrotic toxin, adenylate cyclase toxin, and tracheal cytotoxin. 

Local tissue damage consists of inflammatory changes in the mucosal lining of the respiratory tract, primarily congestion and cellular infiltration with lymphocytes and granulocytes. As the infection progresses, secondary pneumonia or otitis media may occur. Systemic effects of pertussis toxin include sensitization to the lethal effects of histamine and increased secretion of insulin.

#### Clinical Features

##### Symptoms and Signs

Pertussis arises in three distinct sequential clinical stages: the *catarrhal phase*, the *paroxysmal phase*, and the *convalescent phase*. The catarrhal phase begins after an incubation period of approximately 1 to 3 weeks and lasts approximately 1 to 2 weeks. Infectivity is greatest during the catarrhal phase, when the disease is clinically indistinguishable from other upper respiratory tract infections. Signs and symptoms include rhinorrhea, low-grade fever, malaise, and conjunctival injection. A dry cough usually begins at the end of the catarrhal phase. 

The paroxysmal phase begins as fever subsides and cough increases and lasts from 2 to 4 weeks. Paroxysms of staccato coughing occur 40 to 50 times per day. The patient coughs repeatedly in short exhalations followed by a single, sudden, forceful inhalation that produces the characteristic “whoop.” Only one third of adults (range 8–82%) with pertussis develop this whoop, and it is rare in young infants, who may present with apneic episodes and no other symptoms. Paroxysms may be spontaneous, occur more frequently at night, or be precipitated by noise or cold. During the paroxysm, the patient may exhibit cyanosis, diaphoresis, protrusion of the tongue, salivation, and lacrimation. Post-tussive vomiting, syncope, and brief episodes of apnea may occur. Infants may be physically exhausted after a typical paroxysm. Between episodes of coughing, patients do not appear acutely ill.

The convalescent phase is characterized by a residual cough that lasts for several weeks to months. Paroxysms of coughing may be triggered by an unrelated upper respiratory infection or by exposure to a respiratory irritant. This recurrence of coughing does not represent recurrence of pertussis infection.

Atypical presentations may occur in young and preterm infants. Fever is usually not present in uncomplicated newborn pertussis. Tachypnea, apnea, and cyanotic and bradycardic episodes may be the predominant symptoms. Older children and adults who have partial protection from vaccination or previous illness may have a long-lasting intractable dry cough that is frequently misdiagnosed as bronchitis.

Physical examination findings are nonspecific. Tachypnea is variably present and may be related to the degree of pulmonary involvement. Low-grade fever is common during the catarrhal phase, as are conjunctival injection and rhinorrhea. The presence of fever during other stages of illness suggests secondary infection. Petechiae above the nipple line, subconjunctival hemorrhages, and epistaxis may occur because of increased intrathoracic pressure during coughing paroxysms.

Chest examination may reveal rhonchi or clear lung fields; the presence of rales suggests pneumonia.

#### Complications

The major complications of pertussis are pneumonia superinfection, central nervous system (CNS) sequelae, otitis media, and complications related to the paroxysm of coughing. Pneumonia complicating pertussis is a leading cause of death, especially in infants and young children. Aspiration of gastric contents and respiratory secretions may occur during the paroxysm of coughing, whooping, and vomiting. Secondary pulmonary infection may also be a consequence of decreased respiratory tract clearance related to the actions of the *Bordetella* organism and its toxins on bronchial and lung mucosa. Bacterial (*Streptococcus pneumoniae, Streplococcus pyogenes, Haemophilus influenzae, and Staphylococcus aureus*) and viral (respiratory syncytial virus, cytomegalovirus, and adenovirus) superinfections can complicate pertussis infections. A fever during the paroxysmal phase should alert the physician to a possible superinfection.

CNS complications include seizures (0.2–2%) and encephalopathy (0.3%). The causes are unclear but may include hypoxia, hypoglycemia, cerebral petechia, effects of a toxin, or secondary infection by neurotropic viruses or bacteria. CNS hemorrhages may occur as a consequence of the increased cerebrovascular pressures generated during the paroxysm of coughing. Sudden increases in intrathoracic and intra-abdominal pressures can result in several other complications (Box 127-2).

Bradycardia, hypotension, and cardiac arrest can occur in neonates and young infants with pertussis. Severe pulmonary hypertension has increasingly been recognized in this age group and can lead to systemic hypotension, worsening hypoxia, and increased mortality. Intensive care monitoring is recommended for these patients, regardless of how well they may appear on admission.

#### Diagnostic Strategies

The diagnosis of pertussis should be entertained in any patient with prolonged cough with paroxysms, whoops, or post-tussive...
emesis regardless of previous vaccination status. Up to 25% of adults in the United States who have a prolonged cough have serologic evidence of pertussis.13

Ancillary studies are of limited value in the emergency department. During the late catarrhal and early paroxysmal phases, a marked leukocytosis and a characteristic lymphocytosis are often present. The white blood cell (WBC) count of 25,000 to 50,000/mL is not uncommon and may exceed 60,000/mL in infants.13,16 Adults with pertussis frequently do not have the characteristic leukocytosis and lymphocytosis, and some infants and immunocompromised hosts may not be able to mount this response. The chest radiograph may show peribronchial thickening, atelectasis, or pulmonary consolidation.17

Laboratory confirmation of the diagnosis is made by nasopharyngeal culture and PCR, if both are available; sputum and throat swabs are inadequate.18 The Bordetella organism is fastidious, and isolation requires a nicotinamide or Bordet-Gengou medium impregnated with antibiotics to reduce overgrowth of competing bacteria. The slow-growing hemolytic colonies of B. pertussis take 3 to 7 days to appear. A synthetic culture medium is also available. The sensitivity of pertussis cultures is only 20 to 40%. Direct fluorescent antibody techniques are no longer recommended to identify B. pertussis.14 Adults generally come to medical attention late in the disease, at which time cultures are rarely positive (3.6%). PCR is much more likely to identify the organism.

**Differential Considerations**

The differential diagnosis includes acute viral upper respiratory tract infection, pneumonia, bronchiolitis, cystic fibrosis, tuberculosis, exacerbation of chronic obstructive pulmonary disease, and foreign body aspiration. The marked leukocytosis may suggest the diagnosis of leukemia.

**Management**

**Acute Treatment**

Treatment of pertussis is primarily supportive and includes oxygen, frequent suctioning, maintenance of hydration, parenteral nutrition if necessary, and avoidance of respiratory irritants. Patients with suggested pertussis and associated pneumonia, hypoxia, or CNS complications or those experiencing severe paroxysms should also be hospitalized. Children younger than 1 year old should also be admitted because they are not yet fully immunized and have the greatest risk for morbidity and mortality.13 Neonates with pertussis should be admitted to an intensive care unit (ICU), as apnea and significant cardiac complications can occur without warning.17

Antibiotic treatment does not appear to significantly reduce the severity or duration of illness when started in the paroxysmal phase and may have only a minimal effect in the catarrhal phase. The primary goal of antibiotic therapy is to decrease infectivity and carriage. Erythromycin estolate ester is the antibiotic of choice at 40 to 50 mg/kg/day (maximum 2 g/day) in two or three divided doses for 14 days.13,17 Azithromycin (10 mg/kg on day 1 followed by 5 mg/kg on days 2–5), clarithromycin (15 mg/kg/day in two divided doses), and a 7-day course of erythromycin estolate ester are effective alternatives for patients who do not tolerate 14 days of erythromycin well.13,17,19 Trimethoprim-sulfamethoxazole (8 mg/kg/day of trimethoprim) is an alternative for macrolide-allergic patients but efficacy is unproven. Patients should be considered infectious for 3 weeks after the onset of the paroxysmal phase or until at least 5 days after antibiotics are started.14 Strict isolation is recommended during this period.

Corticosteroids, especially in young critically ill infants, may reduce the severity and course of illness, but effectiveness is not well established. Beta2-adrenergic agonists do not reduce the frequency or severity of paroxysmal coughing episodes15,20 but may be helpful in patients with reactive airway disease. Trials with pertussis immune globulin are limited and to date show no proven benefit.21 Standard cough suppressants and antihistamines are ineffective.20

Postexposure prophylaxis, with erythromycin as described previously, is recommended for household contacts of patients with pertussis regardless of previous vaccination status.13 Erythromycin should also be prescribed for any unimmunized person or partially immunized infant with a history of significant exposure to the index case.13

**Vaccination**

Whole-cell and acellular pertussis vaccines are distributed in combination with diphtheria and tetanus toxoids as DPT and DTaP, respectively. The acellular pertussis vaccines contain inactivated pertussis toxin and one or more other bacterial components. The acellular vaccine is as effective as the whole-cell vaccine with fewer adverse reactions reported.22,23 Most recipients develop fever, irritability, behavioral changes, and local discomfort at the site of inoculation. Moderately severe reactions are uncommon but include fever with temperature over 40°C, persistent crying, high-pitched crying, and seizures. Severe neurologic complications (prolonged seizures and encephalopathy) occur rarely but led to decreased use of the whole-cell form of the vaccine and the development of DTaP.23 DTaP has replaced DPT for childhood immunizations, and the whole-cell pertussis vaccine is recommended for use in the United States only when the acellular vaccine is not available.23

Pertussis immunity wanes significantly 6 to 8 years after immunization and 15 years after natural infection,24 causing an increasing incidence of the disease in people older than 15 years. The acellular pertussis vaccine is safe and effective in adolescents and adults, and routine booster immunization is currently recommended by the CDC Advisory Committee on Immunization Practices for persons aged 11 to 18 years.14

**TETANUS**

**Perspective**

**Background**

Tetanus is a toxin-mediated disease characterized by severe uncontrolled skeletal muscle spasms. Involvement of the
muscles of respiration leads to hypoventilation, hypoxia, and death. Dramatic descriptions of this disease date back to ancient Egypt when physicians recognized a frequent relationship between tissue injury and subsequent fatal spasm. 25,26 In 1884 Carle and Rattone produced tetanus in rabbits by injecting material from an acne pustule that came from an infected human. In the same year, Nicolaier isolated the strychnine-like toxin from anaerobic soil bacteria. In 1889 Kitasato obtained pure cultures of spore-forming bacteria that caused tetanus when introduced into animals. 25 One year later, Faber proved that tetanus was a toxin-mediated disease when he induced the illness by injecting animals with bacteria-free filtrates of Clostridium tetani cultures. In the 1890s von Behring and Kitasato discovered tetanus antitoxin in the serum of immune animals and demonstrated its efficacy in preventing disease. Prophylactic injection of this antitoxin provided passive immunity to wounded soldiers during World War I. It was not until the 1930s that an effective vaccine was developed. Large-scale testing during World War II indicated that the tetanus toxoid conferred a high degree of protection against disease.

Epidemiology

Despite the availability of an effective vaccine, tetanus remains endemic worldwide. It is more common in warm, damp climates and relatively rare in cold regions. The global incidence of tetanus is estimated to be between 800,000 and 1 million cases a year, with half occurring in neonates. Eighty percent of these cases occur in Africa and Southeast Asia because of low immunization rates and poor hygiene.26

Since the introduction of vaccination programs in the United States, the incidence of tetanus has steadily declined from 4 cases per million population in the 1940s to 0.095 cases per million population in 2005 (Fig. 127-2).27,28 The highest incidences occur in people older than 60 years (0.35 cases per million population), Hispanic Americans (0.37 cases per million population), and diabetics (0.70 cases per million population). Fifteen percent of cases occur in injection drug users. The overall case fatality rate is 18% but approaches 50% in patients older than 70 years (Fig. 127-3). Cases have been reported in patients who had been fully vaccinated, but in the eight patients from 1998 to 2000, no deaths occurred.29

Tetanus typically occurs as a result of a deep penetrating wound. A history of injury is present in more than 70% of patients, but the injury may be trivial in 50% of patients and unapparent in up to 30% of patients. 25,26,29 The most common portals of entry for the organism are puncture wounds, lacerations, and abrasions. Tetanus has also been reported in association with chronic skin ulcers, abscesses, and otitis media, as well as with foreign bodies, corneal abrasions, abortions, childbirth, and dental procedures. 26,30 Postoperative tetanus has been reported in patients who have undergone intestinal operations and abortions. In these cases the source of bacteria is probably endogenous, as up to 10% of humans harbor C. tetani in the colon.

Inadequate primary immunization and waning immunity continue to be the primary risk factors for tetanus in the United States. As tetanus vaccination of children has improved, older people have accounted for an increasing percentage of reported cases.

Etiology

C. tetani is a spore-forming, motile, slender, rod-shaped, obligate anaerobic bacillus. It stains gram positive in fresh culture but has a variable staining pattern in old cultures and tissue

---

samples. The bacillus can form a single spherical terminal endospore that swells the end of the organism to produce a characteristic drumstick appearance. *C. tetani* is ubiquitous in soil and dust and is also found in the feces of animals and humans. Mature bacilli are highly susceptible to heat and other adverse environmental conditions. Spores are resistant to heating and chemical disinfectants and can survive in soil for months to years. When introduced into a wound, spores may not germinate for weeks because of unfavorable tissue conditions. When injury favors anaerobic growth, the spores germinate into mature bacilli. Only these mature bacilli produce the tetanus toxin that causes clinical disease.

**Principles of Disease**

*C. tetani* is a noninvasive organism. The development of clinical tetanus requires a portal of entry for the infecting spores as well as tissue conditions that promote germination and growth in an immunologically susceptible host. Tetanus-prone wounds are those with damaged or devitalized tissue, foreign bodies, or other bacteria. Under these conditions, *C. tetani* produces the neurotoxin that causes clinical illness. Germination and replication of *C. tetani* can occur without clinical signs of a local wound infection.

*C. tetani* produces the neurotoxin tetanospasmin (TS) at the site of tissue injury. TS first binds the motor nerve ending and then moves by retrograde axonal transport and trans-synaptic spread to the CNS. It binds preferentially to inhibitory (γ-aminobutyric acid [GABA]ergic and glycinergic) neurons and blocks the presynaptic release of these neurotransmitters. Interneurons afferent to alpha motor neurons are affected first. Without inhibitory control, the motor neurons undergo sustained excitatory discharge, resulting in the muscle spasm characteristic of tetanus.

TS may also affect preganglionic sympathetic neurons and parasympathetic centers, resulting in autonomic nervous system dysfunction. The clinical manifestations include dysrhythmias and wide fluctuations in blood pressure. The binding of TS at the synapse is irreversible; recovery occurs only when a new axonal terminal is produced.

**Clinical Features**

**Symptoms and Signs**

The incubation period for tetanus ranges from 1 day to several months. A shorter incubation period portends a worse prognosis. The duration of the incubation period is not useful in making the diagnosis of tetanus because many patients have no history of an antecedent wound.

Four types of clinical tetanus have been described.

1. **Generalized tetanus** is the most common form of the disease and results in spasms of agonist and antagonist muscle groups throughout the body. The classic initial presenting symptom of trismus (“lockjaw”) caused by masseter spasm is present in 50 to 75% of patients. As the other facial muscles become involved, a characteristic sardonic smile (risus sardonius) appears. Other early symptoms include irritability, weakness, myalgias, muscle cramps, dysphagia, hydrophobia, and drooling. As the disease progresses, generalized uncontrollable muscle spasms can occur spontaneously or as a result of minor stimuli such as touch or noise. Spasms may result in vertebral and long bone fractures and tendon rupture. Opisthotonus is a prolonged tonic contraction that closely resembles decorticate posturing. Spasms of laryngeal and respiratory muscles can lead to ventilatory failure and death. Autonomic dysfunction is the major cause of death in patients who survive the acute phase and manifests by tachycardia, hypertension, temperature elevation, cardiac dysrhythmias, and diaphoresis. The illness is progressive, with an increase in symptoms over the first 3 days, persistence of symptoms for 5 to 7 days, and reduction of spasms after 10 days. If the patient survives, recovery is complete after 4 or more weeks. Throughout the course of this horrific illness, patients remain completely lucid unless chemically sedated.

2. **Localized tetanus** is a form of the disease characterized by persistent muscle spasms close to the site of injury. Symptoms may be mild or severe, but mortality is much less frequent than with generalized tetanus. Local tetanus may progress to generalized disease. This form of illness may probably reflect partial immunity to tetanospasmin and may be present for weeks to months before resolution.

3. **Cephalic tetanus** is a rare variant of local tetanus that results in cranial nerve palsies as well as muscle spasms. The palsies precede the spasm in 42% of cases, resulting in frequent misdiagnosis. The most commonly involved cranial nerve is the facial nerve (VII), mimicking Bell’s palsy. Most of these cases occur after facial trauma or otitis media. Patients develop trismus and palsies of cranial nerve III, IV, VII, IX, X, or XII, ipsilateral to the site of local infection. The clinical course is variable. In one third of cases, resolution of symptoms is complete. The remainder progress to generalized tetanus with an overall mortality rate of 15 to 30%.

4. **Neonatal tetanus** is generalized tetanus of the newborn and occurs almost exclusively in developing countries, where maternal immunization is inadequate and contaminated material is used to cut and dress umbilical cords. Symptoms begin during the first week of life and include irritability and poor feeding. Mortality approaches 100% because of the high toxin load for body weight and inadequate medical support in developing countries. Even with limited resources, mortality can be reduced to less than 50% with basic medication and experienced medical and nursing personnel.

The CDC reported one case of neonatal tetanus in the United States between 1998 and 2000. The infant was born at home to an unimmunized mother. The umbilical cord had been treated with bentonite clay. The child was treated and recovered after 19 days of hospitalization.

**Complications**

Acute respiratory failure, the main cause of morbidity and mortality in tetanus, results from respiratory muscle spasms or laryngospasms and airway obstruction. If the patient survives the acute onset of illness and has adequate ventilatory support, autonomic dysfunction becomes the leading cause of death. Autonomic instability occurs several days after the onset of generalized spasms. Disinhibition of the sympathetic nervous system predominates and causes dysrhythmias, hypertension, myocarditis, and pulmonary edema. Dyrsrhythmias and myocardial infarction are the most common fatal events during this phase.

Forceful tetanic muscle spasms can cause vertebral subluxations and fractures, long bone fractures, and shoulder and temporomandibular joint dislocations. Rhabdomyolysis occasionally occurs and can cause acute renal failure. Renal failure may also result from dehydration and sympathetic nervous system hyperactivity. Renal vein thrombosis may cause renal failure in neonatal tetanus.

Secondary infection may occur in the initial inoculating wound or as a complication arising from invasive treatment...
modalities such as mechanical ventilation. Hyperthermia may also result from muscle spasms and sympathetic hyperactivity. Prolonged immobility can lead to deep venous thrombosis and pulmonary embolism. Gastrointestinal complications include peptic ulcers, ileus, intestinal perforation, and constipation. The syndrome of inappropriate secretion of antidiuretic hormone occurs in a small number of patients. Hemolysis has also been reported.

Mortality is a function of the previous immunization status, incubation period, severity and rapidity of onset of symptoms, comorbid disease, age, and the sophistication of medical treatment available. With appropriate intensive care treatment, elder patients may fare as well as their middle-aged counterparts. Long-term physical complications in survivors are rare. The most common persistent problem may be psychological trauma related to the disease and its treatment.

Diagnostic Strategies

The diagnosis of tetanus should be made on clinical grounds alone. Wound cultures for C. tetani are of little value as they are positive in only one third of cases. Even if a positive culture is obtained, it does not indicate whether the bacterium is a toxin-producing strain. There are no laboratory tests to confirm this. If a positive culture is obtained, it does not indicate whether the bacterium is a toxin-producing strain. There are no laboratory tests to confirm or exclude the diagnosis of tetanus. In 1990 the CDC adopted a clinical case definition for the public health surveillance of generalized tetanus: “acute onset of hypertonia or painful muscular contractions (usually of the muscles of the jaw and neck) and generalized muscle spasms without other apparent medical cause (as reported by a health care professional).”

Lumbar puncture may be indicated to exclude meningitis in the neonate when the diagnosis of tetanus is uncertain. A computed tomography scan is helpful in assessing for intracranial pathology. A serum calcium level is helpful to exclude hypocalcemia. Electromyography (EMG) may be useful if the diagnosis of cephalic or localized tetanus is in doubt. 

Differential Considerations

Strychnine poisoning is the only clinical condition that truly mimics generalized tetanus. Strychnine, like TS, antagonizes glycine release, but unlike TS, it has no effect on GABA release. Patients develop opisthotonus while remaining alert. The annual incidences of tetanus and strychnine poisoning are similar in the United States, and serum and urine tests are positive in only one third of cases. Even if a positive culture is obtained, it does not indicate whether the bacterium is a toxin-producing strain. There are no laboratory tests to confirm or exclude the diagnosis of tetanus.

In patients who present with diffuse generalized spasm, the diagnosis of tetanus is less likely to be missed, but ideally the disease should be considered and diagnosed in the early stages to minimize complications and decrease mortality. Some conditions with clinical similarities to tetanus are listed in Box 127-3. Trismus is most commonly caused by intraoral infections. These can be excluded with careful history and physical examination of the oral cavity and teeth. Mandibular dislocation can be ruled out with appropriate radiographs of the mandible and temporomandibular joints. Dys tonic reactions can be differentiated from tetanus by medication history and symptoms that are alleviated by benztprine or diphenhydramine. Patients with ecephalitis usually exhibit an altered mental status. Meningitis can be excluded by examining the cerebrospinal fluid (CSF). Rabies must be considered when there are symptoms of brainstem dysfunction, including dysphagia and respiratory muscle dysfunction. A history of exposure to secretions of an infected animal is the most helpful historical point. In addition, rabies does not cause trismus.

The diagnosis of cephalic tetanus is especially difficult to diagnose when the cranial nerve palsy precedes trismus. The differential diagnosis of cephalic tetanus also includes Bell’s palsy, botulism, cranial nerve palsies, and facial cellulitis with facial nerve compression and ophthalmoplegia.

Management

Acute Treatment

The four treatment strategies for patients with tetanus should be undertaken simultaneously: (1) aggressive supportive care, (2) elimination of unbound TS, (3) active immunization, and (4) prevention of further toxin production. Benzodiazepines are the mainstay of symptomatic therapy for tetanus. These drugs are GABA agonists and indirectly antagonize many of the effects of TS. They have no effect on the inhibition of glycine release by TS. Diazepam is the most extensively studied of these agents, but lorazepam and midazolam are equally effective. Diazepam has a rapid onset of action, a wide margin of safety, and can be given orally, rectally, or IV. It is inexpensive and thus available in most parts of the world. It has a long cumulative half-life and active metabolites that can cause prolonged sedation and respiratory depression. The IV formulations of diazepam and lorazepam contain propylene glycol, which, at high doses, can produce lactic acidosis. Gastrointestinal delivery of these agents is limited by motility problems associated with tetanus. Midazolam has a short half-life and does not contain propylene glycol, but it must be given by continuous infusion and is cost-prohibitive in most areas of the world. Propofol infusion is effective, but it is also expensive and patients may not tolerate the lipid vehicle. Neuroleptics, barbiturates, and intrathecal baclofen have no advantage over benzodiazepines. Dantrolene is a direct muscle relaxant without CNS activity. It has been reported as an adjunctive agent for muscle spasms and may decrease the need for mechanical ventilation. Magnesium sulfate infusion has been advocated as both adjuvant
and first-line therapy for tetanus. Alone or in combination with other agents, it improves spasm control and may alleviate some of the autonomic instability associated with tetanus toxicity.\(^\text{28}\)

If spasm cannot be controlled with these regimens or if any signs of airway compromise develop, the patient should receive neuromuscular blockade and mechanical ventilation. Although succinylcholine can be used in the \emph{initial} phase of the disease, the clinician must be aware of the risk of severe hyperkalemia resulting from its use in any neuromuscular disease. This effect does not begin until about 4 days after the onset of disease.\(^\text{29}\) Long-acting nondepolarizing agents are preferred, even in the \emph{initial} phase. Pancuronium has traditionally been used, but it is an inhibitor of catecholamine reuptake and may worsen autonomic instability.\(^\text{26}\) Vecuronium and rocuronium are shorter acting and are without significant cardiovascular side effects but require continuous infusion. Whichever agent is used, adequate sedation should be provided and neuromuscular blockade should be withheld at least once a day to assess the patient’s status. All intubated patients should be considered for early tracheostomy to decrease reflex spasms caused by the endotracheal tube.\(^\text{26,32}\)

Autonomic instability requires monitoring and aggressive treatment. Sympathetic hyperactivity can be treated with combined alpha- and beta-adrenergic antagonists such as labetalol or propranolol. The use of beta-antagonists alone can lead to unopposed alpha-activity resulting in severe hypertension.\(^\text{30}\) If beta-antagonists are necessary, a short-acting agent such as esmolol should be used.\(^\text{29}\) Clonidine has shown variable success at modulating sympathetic outflow.\(^\text{x26}\) Morphine and magnesium sulfate infusions as well as spinal anesthesia and intrathecal baclofen have all been shown to improve autonomic dysfunction.\(^\text{25,26}\) Diuretics should be avoided for blood pressure control as volume depletion can worsen autonomic instability. Bradydysrhythmia should be treated with temporary pacing. Atropine and sympathomimetic drugs should be used with caution as the autonomic instability is essentially due to catecholamine excess.\(^\text{32,34}\)

**Elimination of Unbound Tetanospasmin and Active Immunization.** Human tetanus immunoglobulin (HTIG) and Td should be administered as soon as possible to all patients with possible tetanus. Tetanus immunoglobulin (TIG) does not neutralize toxin already present in the nervous system, nor does it treat any existing symptoms. HTIG neutralizes any circulating toxin as well as toxin at the site of production and reduces mortality. TIG should be administered at a site separate from the toxoid. Dosage recommendations vary (500–10,000 units of TIG), but multiple injections are stimuli for spasm and most authorities note that 500 units is as effective as higher doses. Adult and pediatric doses are the same.\(^\text{25,30}\) If the larger doses are used, they should be given in divided doses. Administration of a portion of the TIG proximal to the site of inoculation is often recommended but has not been studied.\(^\text{25-27}\) Protective antibody levels are achieved 48 to 72 hours after administration of TIG. Because the half-life of TIG is 25 days, repeated doses are not needed. The preparation of TIG available in the United States is not licensed for intrathecal administration, which is of no proven benefit.\(^\text{25,27,32}\)

**Prevention of Further Toxin Production.** Toxin production is eliminated by treating the \emph{C. tetani} infection. Wound debridement and antibiotic administration can cause a transient release of TS, and the emergency physician should consider delaying these measures until after the HTIG is administered. The wound should be debrided and irrigated and any foreign bodies removed. Metronidazole (500 mg orally or IV every 6 hours) is the antibiotic of choice for \emph{C. tetani}. Pediatric doses of metronidazole depend on age and weight. (Neonates < 2000 g and 0–7 days: 7.5 mg/kg IV/PO every 24 hours; Neonates < 2000 g and 8–28 days: 7.5 mg/kg IV/PO every 12 hours; Neonates ≥ 2000 g and 0–7 days: 7.5 mg/kg IV/PO every 12 hours; Neonates > 2000 g and 8–28 days: 15 g IV/PO every 12 hours; Infants and children: 15–30 mg/kg/day IV divided every 6 hours, maximum 4 g/day.)\(^\text{27}\) Penicillin has traditionally been used to treat tetanus and has good in vitro and in vivo activity against \emph{C. tetani} but also has GABA antagonist activity and may potentiate the effects of TS. Metronidazole has better penetration into devitalized tissue and abscesses than penicillin and is superior in terms of recovery time and effect on mortality. Macrolides, doxycycline, chloramphenicol, and tetracycline are effective alternatives in metronidazole-allergic patients.\(^\text{27,30,32}\)

**Vaccination**

Tetanus toxoid is an inactivated form of TS, and vaccination confers protective antibody levels in nearly 100% of people who receive three doses. Immunity wanes between 5 and 10 years after completion of the series. In high risk patients such as elders, IV drug users, and patients with human immunodeficiency virus and other causes of immunocompromise, immunity wanes more quickly and the response to vaccine is less brisk.

Adults with an uncertain history of a complete primary immunization series should receive a primary series. The standard vaccination program consists of a primary series of three tetanus toxoid doses, followed by booster doses every 10 years. Age-specific guidelines for tetanus prophylaxis have been developed by the Immunization Practices Advisory Committee and published by the CDC (Tables 127-1 to 127-3).\(^\text{28}\)

Tetanus vaccination should be updated for all patients who come to the emergency department for management of a wound, even if the presenting complaint is not wound-related. Patients with unknown or uncertain immunization status should be considered to have no previous tetanus immunization. Those younger than 7 years should receive diphtheria-tetanus or DTaP. Patients 7 years of age or older should receive Td instead of DT because adverse reactions from the larger doses of diphtheria toxoid in DT are more common in older individuals.

HTIG prophylaxis (250 units IM) is recommended for unimmunized and underimmunized patients with wounds at high risk for tetanus (>6 hours old, greater than 1 cm deep, contaminated, stellate, denervated, ischemic, infected).\(^\text{30}\) When tetanus toxoid and HTIG are given concurrently, separate injection sites should be used. The only contraindication to tetanus and diphtheria toxoids is a history of a neurologic or severe hypersensitivity reaction to a previous dose. Adverse reactions to tetanus toxoid and tetanus-diphtheria toxoids occur commonly and may be the result of the preservative thiomersal. The most common side effects are minor: local swelling, pain, erythema, pruritus, fever, nausea, vomiting, malaise, and nonspecific rash. Local reactions do not preclude future use of toxoid. Serious anaphylactic reactions are rare. If a patient who requires immunoprophylaxis gives a history suggestive of a neurologic or severe anaphylactic reaction, HTIG should be administered alone to protect the patient from developing tetanus as a result of the present injury. HTIG does not confer active immunity, and such patients should be referred to an allergist for measurement of antibody levels, antitoxin desensitization, and immunization. No evidence exists that tetanus or diphtheria toxoids are teratogenic. HTIG is not contraindicated in pregnancy. For inadequately immunized patients of any age, referral should be made to ensure that the patient receives the remainder of the immunizations required.\(^\text{38}\)

Botulism

Epidemiology

Seven types of toxin (A through G) are produced by C. botulinum, but only types A, B, E, and F cause illness in humans, and types C and D cause disease in animals. Type G has been found in soil but has not been definitively linked to human or animal outbreaks. C. botulinum spores are found throughout the United States. Type A is found more commonly in the west and type B in the east. Type E is frequently associated with fish products. An average of 110 cases a year are reported to the CDC; 25% are food-borne botulism, 72% are infant botulism, and the rest are wound-related. Despite the ubiquitous nature of botulinum spores and the variety of possible routes of toxin entry, the incidence of disease is low.

Typical food-borne botulism results from the ingestion of preformed heat-labile toxin rather than ingestion of spores or live bacteria. Food-borne botulism usually results from expo-
sure to home-canned foods that are inadequately preserved and undercooked, but occasionally large outbreaks occur after the ingestion of contaminated food at restaurants or from commercial sources. A variety of preserved foods have been implicated, and botulism has also been reported to result from ingestion of improperly prepared and stored fresh foods.\(^{42}\)

Infant botulism is the most common form of the illness in the United States. It occurs in children younger than 1 year with a peak incidence between the ages of 2 and 6 months. In contrast to food-borne botulism in adults, infant botulism is caused by the ingestion of spores with in vivo production of toxin. Honey and, to a lesser extent, corn syrup have been implicated as sources of *Clostridium botulinum* spores in infant botulism. Soil and vacuum cleaner dust have also been implicated, but the source of ingestion remains unknown in most cases. Types A and B botulinum toxins have been responsible for all infant cases.\(^{43}\)

Some investigators have explored a possible relationship between infant botulism and the sudden infant death syndrome, but a 10-year prospective study of 248 infants diagnosed with sudden infant death syndrome revealed no cases attributable to *C. botulinum*.\(^{44}\)

Wound botulism once accounted for approximately one botulism case per year, but the increased use of black tar heroin has resulted in a dramatic increase in cases. In 1994, 11 of the 53 adult botulism cases reported to the CDC were wound botulism. All occurred among injection drug users in California. Toxin types A and B are the causative agents.\(^{45}\)

Unclassified, hidden, or adult infectious botulism is a rare illness that is analogous to infant botulism. The *Clostridium* bacterium produces its toxin in vivo. Patients with compromised gastric acidity, disturbances of gastrointestinal motility, or abnormal gastrointestinal bacterial flora may be susceptible to in vivo production of botulinum toxin. Between 1976 and 1996, 39 cases were reported to the CDC. Toxin types A, B, and F were identified in these patients.\(^{46}\)

Inadvertent botulism is an iatrogenic form of the disease that occurs in patients who have been treated with injections of botulinum toxin for dystonia and other movement disorders and for cosmetic purposes. Inadvertent generalized weakness as well as unintentional focal weakness may be seen.\(^{40}\)

The potential exists for botulinum toxin to be used as an offensive biologic weapon. It is highly potent and easy to produce. The Aum Shinrikyo, responsible for the 1995 sarin gas attack on the Tokyo subway, have produced and dispersed aerosols of botulinum toxin in Japan on at least three occasions between 1990 and 1995. In 1995, Iraq admitted to the United Nations that it had produced 19,000 L of concentrated botulinum toxin and loaded approximately 10,000 L into warheads. These 19,000 L are not fully accounted for and constitute three times the amount needed to kill the entire human population by inhalation.\(^{47}\)

### Principles of Disease

#### Etiology

*C. botulinum* is a strictly anaerobic, large gram-positive, rod-shaped organism. It forms spores that germinate under certain environmental conditions. The bacteria may then produce a potent exotoxin that is responsible for the disease. Each strain of *C. botulinum* produces a specific toxin type—A, B, C, D, E, F, or G. Only types A, B, E, and rarely F produce disease in humans.\(^{39}\) Botulinum toxins are the most potent known biologic compounds.\(^{46}\) Doses as small as 0.09 to 0.15 µg IV or 0.7 to 0.9 µg inhaled can cause death in a 70-kg human.\(^{45}\) The toxins are heat-labile. Heating at 85°C for 5 minutes destroys any botulism toxin. Consequently, heating toxin-contaminated food just before ingestion prevents food-borne botulism. Spores are highly heat-resistant, however, and can survive at a temperature of 100°C for several hours.\(^{42}\)

#### Pathophysiology

Food-borne botulism results from ingesting food that contains preformed toxin. Toxin-contaminated food may have a normal appearance and taste or exhibit signs of food spoilage caused by proteolytic enzymes produced by the type A and B strains. Because of the tremendous potency, one taste can expose a person to enough toxin to cause clinical illness. Digestive enzymes do not destroy preformed toxin. Infant and adult infectious botulism results from in vivo bacterial elaboration of toxin in the gastrointestinal tract. Achlorhydria and recent antibiotic use predispose the gastrointestinal tract to colonization with *C. botulinum*. Wound botulism results from inoculation with preformed toxin for medical purposes. Primate studies indicate that aerosolized botulinum toxin can also be absorbed systemically through the respiratory tract.\(^{40,46}\)

The neurotoxin produced by *C. botulinum* is similar in structure and function to the TS toxin produced by *C. tetani*, but the clinical effects differ dramatically. TS targets inhibitory interneurons in the CNS, causing generalized muscle spasm, whereas botulinum toxin targets peripheral neuromuscular junctions and autonomic synapses, thereby causing a flaccid paralysis.\(^{45}\) When botulinum toxin is absorbed from the entry site, it circulates until it reaches the neurons. The toxin binds to the presynaptic nerve membrane, becomes internalized, and then inhibits the release of acetylcholine, resulting in neuromuscular blockade. This interference with neurotransmission occurs predominantly at the cholinergic synapses of the cranial nerves, autonomic nerves, and neuromuscular junction. Clinically, this is manifested by cranial nerve palsies, parasympathetic blockade, and a descending, flaccid paralysis. Once affected with type A toxin, the nerve is permanently damaged, and recovery requires axonal regeneration and the formation of new synapses, which may take several months. Recovery after type F toxin is substantially faster.\(^{40,41}\)

#### Clinical Features

##### Symptoms and Signs

*Food-borne botulism* is the prototype for understanding the clinical signs and symptoms of all forms of botulism. Symptoms begin approximately 18 to 36 hours (range, 6 hours to 8 days) after the ingestion of toxin-containing food. A shorter incubation period is associated with a more severe form of illness. Early symptoms include weakness, malaise, lightheadedness, nausea, vomiting, and constipation. These symptoms are generally not severe and occur in fewer than half of the patients.\(^{46}\)

Neurologic symptoms may begin at the same time or be delayed in onset for several days. The cranial nerves are first affected. Patients experience diplopia, blurred vision, dysphagia, and dysarthria. Vertigo is also a common symptom. Next, a symmetrical descending muscular weakness occurs, involving the upper and lower extremities and the muscles of respiration. Blockade of the cholinergic fibers of the autonomic nervous system leads to a variety of symptoms. Decreased salivation causes a dry mouth, which may be so severe that the patient complains of a painful tongue and sore
throat. Ileus and urinary retention may also occur. In one emergency department series of patients with food-borne botulism, all had at least three of the following four symptoms: weakness, dry mouth, double vision, and difficulty speaking. This constellation of symptoms should prompt the emergency physician to inquire about the ingestion of home-canned or improperly prepared food, as well as the presence of similar symptoms in family members or friends.39-40

The patient with botulism is usually alert and afebrile unless secondary infection is present. Postural hypotension may be present. Ocular signs are prominent and include ptosis, extraocular palsies, and markedly dilated and fixed pupils; the absence of ocular abnormalities does not exclude the diagnosis. The oropharynx may be erythematous, with dry mucous membranes.39 The gag reflex is depressed or absent.

Muscle weakness is usually present and varies from mild to severe. Neck muscles are often weak. Upper extremity muscles are more affected than those of the lower extremity. Proximal muscles are weaker than distal muscles. Deep tendon reflexes may be normal, symmetrically decreased, or absent. The sensory examination is normal. The abdomen may be distended with hypoactive or absent bowel sounds. Bladder distention may be apparent on examination. Respirations may be tachypneic and shallow or normal. In advanced illness, signs of respiratory failure may be present.39

A typical presentation of food-borne botulism has been reported, and certain serotypes produce distinct variations in the pattern of symptoms. Type A disease may be more severe and is more commonly associated with bulbar findings and upper extremity weakness. Types A and B disease may rarely cause a decreased level of consciousness. Type E is associated with a greater incidence of gastrointestinal symptoms.39

The presentation of infant botulism is different from that of food-borne botulism. Constipation is a common presenting complaint, followed by several days to weeks of poor feeding, weak cry, loss of head control, and hypotonia. On physical examination, patients have decreased muscle tone and depressed deep tendon reflexes. Cranial nerve involvement causes alterations in facial expression, ptosis, and extraocular palsies. Respiratory failure occurs in 50% of patients. Fever is absent unless secondary infection is present.40-43

Wound botulism has some notable differences from food-borne botulism. The incubation period is longer, from 4 to 14 days, because the toxin must be produced within the wound after the spores have germinated. If the wound is infected, the patient may be febrile. Gastrointestinal symptoms are notably absent in wound botulism.

The clinical presentation of unclassified (adult infectious) botulism is similar to that of food-borne botulism, although the mortality rate in the former is significantly greater. Recovery from botulism is slow, and survivors are hospitalized for several weeks to months.39-40

Complications

Complications from botulism are related to respiratory failure and problems associated with prolonged intensive care management. The major cause of death from botulism is respiratory failure resulting from weakness of the respiratory muscles. Aspiration of oral secretions and gastric contents because of loss of protective airway reflexes can occur. In the past 50 years, the overall mortality rate has decreased from 50% to less than 8% with modern intensive care. In patients who recover, muscle strength and endurance may not return to normal for up to 1 year, and persistent psychological problems are common.39-41

Diagnostic Strategies

The initial diagnosis of botulism is clinical and should be considered in any patient who presents with the constellation of gastrointestinal, autonomic, and cranial nerve dysfunction. Bilateral cranial nerve involvement and the progression of neurologic findings should increase clinical suggestion. Routine laboratory studies are of no value in the diagnosis. If a lumbar puncture is performed, the CSF in patients with botulism is normal or may show a slight elevation of protein.39

The diagnosis is confirmed by detecting (1) botulinum toxin in the patient’s blood; (2) botulinum toxin or C. botulinum in the gastric contents, stool, or wound of the patient; or (3) toxin or organisms in the suspected food source. Because most hospital laboratories are unable to process such specimens, the local health department and CDC should be notified for specific instruction on the handling of specimens. Ideally the specimens should be obtained prior to administration of antitoxin. Serial measurements of the patient’s vital capacity are helpful in recognizing deteriorating ventilatory function.39,40,48

EMG can detect electrophysiologic abnormalities consistent with the diagnosis of botulism. EMG may also be useful in differentiating botulism from other paralytic illnesses. The EMG signature of botulism is decreased amplitude of the compound muscle action potential in response to a supramaximal stimulus and facilitation of the muscle action potential with repetitive nerve stimulation. Not all motor units are affected, and normal test results do not exclude the diagnosis.39

Differential Considerations

The differential diagnosis of adult botulism includes a wide variety of illnesses. Commonly, the first presenting case is misdiagnosed because early symptoms suggest pharyngitis or gastroenteritis, both of which can affect several members of a single household. Only after one or more cases progress to classical botulism is the diagnosis usually suggested.

Botulism must be differentiated from other illnesses that cause paralysis. In Guillain-Barré syndrome, weakness usually starts distally and ascends, paresthesias may be present, and the CSF protein may be elevated. Tick paralysis is an ascending paralysis, notable for a lack of bulbar involvement and the presence of a tick. In myasthenia gravis, eye signs are also prominent, but pupillary response is preserved, no autonomic symptoms are present, and weakness responds to the administration of edrophonium. Of note, minimal improvement in weakness after the administration of edrophonium has been reported in botulism.39 Poliomyelitis causes fever, asymmetrical neurologic signs, and CSF abnormalities. Diphtheria can be distinguished by the prolonged interval between pharyngitis and neurologic symptoms. Eaton-Lambert syndrome does not usually involve bulbar muscles. Cerebrovascular accidents of the brainstem have an acute onset and asymmetrical, neuroanatomically localizing signs and symptoms.39,40

Certain toxins must also be considered in the differential diagnosis of botulism. Anticholinergics (atropine, belladonna, jimson weed) cause pupillary dilation and dry, red mucous membranes but also cause delirium with alterations in mental status. Organophosphate insecticides have a characteristic odor, and poisoning causes fever and altered mental status. Dystonic reactions are self-limited and respond to diphenhydramine or benzotropine. Neurovascular blockade from the administration of aminoglycosides is distinguished by the medication history. Heavy-metal poisoning produces changes in mental status. Magnesium toxicity may mimic botulism, but the history and serum magnesium levels distinguish these.
entities. In paralytic shellfish poisoning, paresthesias are prominent, a history of shellfish ingestion is present, and recovery occurs within 24 hours.

Infant botulism has a broader differential diagnosis. Common illnesses that mimic the presentation of infant botulism include sepsis, various viral illnesses, dehydration, encephalitis, meningitis, and failure to thrive. Neurologic illnesses such as Guillain-Barré syndrome, myasthenia gravis, and poliomyelitis should also be considered. Hypothyroidism, hypoglycemia, diphtheria, and toxin exposures are all part of the differential consideration, as are less common conditions such as inborn errors of metabolism, congenital muscular dystrophy, and cerebral degenerative diseases.

Management

The treatment of botulism consists of supportive care and specific treatment with antitoxin and other medications to block the effects of the toxin. All patients with suggested botulism should be admitted to the hospital and placed in an ICU as respiratory failure may develop rapidly and insidiously. When signs of ventilatory failure develop, early endotracheal intubation should be performed. A decrease in vital capacity to less than 12 mL/kg is an appropriate criterion for intubating a patient. Ileus should be treated with nasogastric suction and urinary retention with an indwelling urinary catheter. Fortunately, the autonomic dysfunction of botulism is much less severe than that of tetanus and rarely requires any intervention.

Saline enemas and cathartics have been recommended by some authors to cleanse the gastrointestinal tract of residual toxin. Cathartics should not be given in the presence of ileus. Magnesium-containing cathartics should be avoided because elevated serum magnesium levels can exacerbate muscle weakness. Special care must be taken when using gastrointestinal clearance in infants with botulism. Because the source of toxin is outside the gastrointestinal tract in wound botulism, bowel decontamination is not indicated.

Equine trivalent antitoxin contains antibodies to toxin types A, B, and E. It should be administered intravenously as soon as possible after appropriate laboratory specimens have been obtained. It neutralizes only circulating toxin and has no effect on bound toxin. Early administration prevents the progression of illness, decreases hospital length of stay, prevents respiratory failure, and shortens the duration of respiratory failure in patients with severe disease. Antitoxin can be obtained from the CDC or state health department. After skin testing for hypersensitivity, one 10-mL vial should be given IV. This dose results in circulating antitoxin levels capable of binding circulating toxin concentrations many times in excess of those reported in botulism patients. The serum half-life is 5 to 8 days. For these reasons, and contrary to the information in the package insert, only one vial of antitoxin is required. Repeated doses are unnecessary and may increase the risk of hypersensitivity reactions, which occur in approximately 9% of patients.

Antitoxin is generally not recommended in infant botulism because efficacy has not been demonstrated and because of the risk of anaphylaxis to horse serum. A human botulism immunoglobulin (BabyBIG) is pooled plasma from immunized adults with high titters of antibodies to toxins A and B. It was approved by the FDA for the treatment of infant botulism in October 2003. BabyBIG shortens hospital length of stay by a mean of 3.1 weeks and mechanical ventilation by a mean of 1.7 weeks. It can be obtained by calling the California Department of Health Services’ Infant Botulism Treatment and Prevention Program at 510-231-7600.

Antibiotics are not currently recommended for food-borne botulism and may increase cell lysis and promote toxin release. Because the source of toxin is in vivo production within an infected wound, débridement and antibiotic administration should be considered only after antitoxin has been administered. Otherwise, the use of antibiotics should be limited to treating secondary infections (e.g., aspiration pneumonia) that may develop. Antibiotic treatment of both infant and wound botulism has no proven benefit. If an antibiotic is used for any reason in a botulism patient, all attempts should be made to avoid the aminoglycosides and tetracyclines because they can impair neuron calcium entry and worsen the effects of botulinum toxin.

Guandine hydrochloride may enhance the release of acetylcholine from terminal nerve fibers. For this reason, it has been recommended as an experimental component of botulism therapy.

Disposition

All patients with possible botulism should be admitted to the hospital and placed in an ICU as respiratory failure may develop rapidly and insidiously. An infectious disease specialist should be consulted for management issues. The CDC should be called for assistance in any case of suggested botulism. The CDC can be reached by calling 404-639-3311 (days) and 404-639-2540 (nights, weekends, and holidays). State and local health departments may also be helpful in investigating and preventing major epidemics. Area emergency departments should be alerted so that subsequent cases can be looked for and diagnosed.

PNEUMOCOCCEMIA

Perspective

Background

More than a century after the identification of Streptococcus pneumoniae as a pathogen in human disease and more than 80 years after the discovery of antibiotics, pneumococcus remains a significant cause of morbidity and mortality worldwide. Pneumococcaemia is defined as the presence of S. pneumoniae in the blood. The clinical presentation ranges from a mild illness to a fulminant, life-threatening, systemic syndrome. S. pneumoniae also causes a myriad of localized infections, including otitis media, pneumonia, meningitis, and, less commonly, endocarditis, septic arthritis, and peritonitis.

S. pneumoniae was discovered in 1881 by Sternberg in the United States and simultaneously by Pasteur in France. By the late 1880s it was referred to as “pneumococcus” because it was the most common cause of lobar pneumonia. In 1884 Friedländer described pneumococccemia. In 1902 Cole published the first case reports of pneumococccemia, including a patient who had meningitis and arthritis without pneumonia. In the early 20th century, Maynard, Lister, Wright, and others demonstrated a decreased incidence of pneumonia after inoculating miners with killed pneumococci. In the 1920s, Heidelberg and Avery showed that antibodies to the surface capsular polysaccharide conferred immunity to pneumococcal disease. Two routes to bacteremia were described. Wandel described the migration of S. pneumoniae from the lung to the bloodstream by way of the lymphatic system. In 1964, Robert Austrian described bacteria passing directly from the upper respiratory tract (middle ear or sinus) to the subarachnoid space, then through the arachnoid villi and into the venous sinus.
An *S. pneumoniae* vaccine was initially developed in the 1940s but was not produced commercially because of the availability of penicillin. The first vaccine was not licensed for use in the United States until 1977. This 14-valent pneumococcal vaccine was replaced in 1983 by a 23-valent vaccine for use in people older than 2 years. The heptavalent conjugate vaccine (Prevnar) is now available and licensed for use in infants younger than 2 years and for other high-risk patients.53

**Epidemiology**

*S. pneumoniae* remains a substantial cause of serious illness despite the availability of antibiotics and vaccines. Pneumococcal infection appears sporadically in normal individuals and in patients with impaired host defenses. Epidemics of pneumococcal infection occur rarely, although bacterial serotypes may cluster by geographic area. Most cases of pneumococcal infections are community-acquired, and the peak incidence is in winter.49

Invasive pneumococcal disease (IPD) is defined as isolation of *S. pneumoniae* from a normally sterile site such as blood, pleural fluid, or CSF.49 In 1997, the CDC estimated 15 to 30 cases per 100,000 population annually in the United States for all people, 50 to 83 cases per 100,000 population annually for those older than 65 years, and 160 cases per 100,000 population annually for children younger than 2 years. Rates were three- to fivefold higher in black adults (49–58 cases per 100,000 population) than whites. Rates were even higher among Alaskan natives at 74 and 624 cases per 100,000 population for adults and children younger than 2 years, respectively. The highest incidence in the United States occurred among Apache Native Americans, with an overall annual incidence of 156 and 2396 cases per 100,000 population for adults and children younger than 2 years, respectively.51 The introduction of the heptavalent vaccine for infants has decreased the incidence of IPD by 65 to 84% in children younger than 2 years in all populations studied.52-56 This decline is almost entirely attributable to the fact that the vaccine is 97% effective at providing immunity to the seven serotypes included.57 The IPD in these studies in almost entirely due to nonvaccine serotypes, with particular concern recently attributed to multidrug-resistant serotype 19A. Ongoing surveillance will determine the need to change the serotypes included in the vaccine.49,58

Pneumococemia occurs in 10 to 25% of patients with pneumococcal pneumonia, and the lungs are the most common source, accounting for about 71% of pneumococemia in adults. Other sources include the meninges (8%) and the sinuses or middle ear (4%). Bacteremia is primary in 18% of adults, but a much higher percentage of children. People at higher risk for pneumococemia include those with chronic respiratory or cardiovascular disease; chronic alcohol abusers; patients with cirrhosis, diabetes mellitus, or an absent or functionally impaired spleen (i.e., those with splenectomy or sickle cell disease); those receiving immunosuppressive therapy; and those with chronic renal failure, nephrotic syndrome, organ transplantation, lymphoma, Hodgkin’s disease, multiple myeloma, and acquired immunodeficiency syndrome (AIDS).51 Pneumococcus is spread from person to person by close contact, and crowded living conditions are associated with epidemics.49

The mortality rate from pneumococemia is approximately 15 to 20% for young adults and 30 to 40% for elders, those with underlying disease, and those with localized infections such as meningitis.51 The case fatality rate is significantly lower for children (1–11%).51 The overall mortality rate from pneumococemia may increase in the future because of the increasing number of elders and AIDS patients and the emergence of antibiotic-resistant strains.

**Principles of Disease**

**Etiology**

Pneumococcemia is caused by *S. pneumoniae*, an encapsulated, gram-positive facultative anaerobic coccus that occurs in pairs and chains. Antigenic differences in the polysaccharide capsule separate *S. pneumoniae* into 90 serotypes.49 In the United States, the seven serotypes present in Prevnar account for 80% of invasive disease in children younger than 6 years and 50% of invasive disease in people older than 6 years. Worldwide, 10 capsular types account for 62% of invasive disease.57-59

**Pathophysiology**

*S. pneumoniae* enters the blood by one of two routes: (1) It begins as a pulmonary infection and spreads to the mediastinal lymph nodes, into the thoracic duct, and then into the circulation. (2) It colonizes or causes infection in the upper respiratory tract and spreads to the subarachnoid space through the arachnoid villi to the venous sinus and into the blood (with or without meningeal involvement). *S. pneumoniae* bacteremia causes a clinical picture that ranges from a minor febrile illness to life-threatening septic shock. Different capsules of *S. pneumoniae* confer varying levels of resistance to phagocytosis, resulting in a spectrum of virulence among these serotypes. Multiple virulence factors contribute to adherence to tissues, inhibition of phagocytosis, activation of complement, and stimulation of cytokines.49

The diversity of individual clinical reactions to pneumococemia is not well understood. Host defenses rely heavily on antibody and complement production, and people who have impaired humoral immunity are more susceptible to invasive pneumococcal disease. In patients with pneumococcal infections, antibodies specific to the capsule serotype develop within several days of onset of infection. This response occurs approximately 30 days after a patient receives the pneumococcal vaccine.49 Patients who demonstrate substantial host resistance are able to develop active immunity, and it is clear that some children can spontaneously clear culture-proven pneumococemia.60

**Clinical Features**

**Symptoms and Signs**

The clinical presentation of pneumococemia ranges from mild illness to fulminant disease, progressing to death within several hours. Occult bacteremia arises as a febrile illness in which the only direct indication of pneumococemia is a positive blood culture (most often at 24–48 hours). Sepsis is the systemic response to infection, manifested by two or more of the following: (1) temperature greater than 38°C or less than 36°C, (2) heart rate greater than 90 beats per minute, (3) respiratory rate greater than 20 breaths per minute or partial pressure of carbon dioxide in arterial gas less than 32 mm Hg, and (4) WBC count greater than 12,000/mm³, less than 4000/mm³, or greater than 10% immature (band) forms.49 Patients may present with lethargy, signs of poor tissue perfusion, cyanosis, and hyperventilation or hyperventilation. Either occult bacteremia or sepsis can occur in conjunction with a localized infection.

The history should include a description of symptoms, including fever, chills, cough, shortness of breath, headache, and rash; a review of systems; and any recent use of antibiotics. The shaking chills and fever that occur with pneumococcemia are believed to be caused by a toxin. There should be an assessment of the patient’s social situation, including avail-
ability of caregivers, transportation to medical care, and the ability to comply with discharge instructions.

In children, the clinical presentation of pneumococcal meningitis is similar to that of other common febrile illnesses. Although signs of focal infection such as pneumonia may be present, often the only indication of pneumococcal infection is fever or other signs of bacterial toxicity.

Most adult patients have fever or hypothermia. Cough, rigors, pleuritic pain, and gastrointestinal symptoms occur in approximately one third of adult patients. Many patients complain of vague, nonspecific constitutional symptoms similar to those of common viral illnesses. Fever (temperature >38.5°C) occurs in 90% of younger patients but in fewer than 60% of those older than 65 years. Patients with signs of sepsis have an increased risk for a fulminant course with rapid deterioration.61,62

Findings on physical examination vary with the site, if any, of primary infection. Pneumonia is the primary source of infection in 71% of adults and 37% of children. The physician should also evaluate for signs of otitis media, sinusitis, and meningitis. Pneumococcal meningitis is considered primary in 18% of adults and 30% of children, so lack of localized infection as a source does not rule out IPD.49,63

Complications

Cardiovascular collapse can occur with fulminant pneumococcal sepsis. Patients who develop severe illness from pneumococcal infection may have end-organ damage from inadequate perfusion, disseminated intravascular coagulopathy (DIC), septic emboli, and other complications. These include respiratory failure, meningitis, hypothermia, gastrointestinal bleeding, hepatic coma, renal failure, and myocardial infarction.62

Pneumococcal meningitis occasionally results in hematogenous seeding, which causes sepsis with meningitis, shock, and other complications. These include respiratory failure, meningitis, hypothermia, gastrointestinal bleeding, hepatic coma, renal failure, and myocardial infarction.62

Pneumococcal meningitis is considered primary in 18% of adults and 30% of children, so lack of localized infection as a source does not rule out IPD.49,63

Diagnostic Strategies

The only test specific for pneumococcal meningitis is a blood culture that grows S. pneumoniae. Ancillary testing of adults with suggested meningitis should include a complete blood count with differential, blood cultures, urine culture and sensitivity, electrolytes, glucose, serum creatinine, and blood urea nitrogen. A chest radiograph may demonstrate pneumonia as the source of infection. Sputum Gram’s stain, culture, and sensitivity testing, if pneumococcus is suggested, are of questionable value in the emergency department but may be useful for continued inpatient care. For sputum specimens to be of value, they should be collected before instituting antimicrobial therapy; however, therapy should not be significantly delayed for the sole purpose of obtaining sputum.69 Antigen testing of urine for pneumococcal polysaccharide is up to 100% sensitive in IPD.65

If the patient appears to be toxic or has signs of respiratory compromise, an arterial blood gas and a coagulation profile should be obtained. If signs of meningitis or alterations in mental status are present, a lumbar puncture should be performed. A Gram’s stain of the buffy coat may be positive in cases of overwhelming pneumococcal sepsis.63 The WBC count is usually elevated. A normal or low WBC count is suggestive of more serious disease, as are hypoxemia and hypercarbia. Musher and colleagues demonstrated an increased mortality rate in patients with serum creatinine levels higher than 2.0 mg/dL, bilirubin levels higher than 1.5 mg/dL, and albumin levels less than 2.5 g/dL.65

Differential Considerations

Pneumococcal meningitis in its more benign presentation must be differentiated from other febrile illnesses, such as viral infections. The combination of clinical findings and culture results enables the emergency physician to distinguish between bacteremia and meningitis of other origins. The presence of fever and shock, with or without a distinct rash, suggests the possibility of sepsis caused by Haemophilus influenzae, Neisseria meningitidis, and other streptococcus types. The presence of confirmed pneumococcal meningitis does not exclude other diagnoses, such as influenza and lung cancer.49

Management

Acute Treatment

Managing pneumococcal meningitis consists of stabilizing life-threatening conditions, eradicating the infection, and treating predisposing or coexisting conditions. The decision to initiate antibiotic therapy for pneumococcal meningitis is often made with limited objective data, which include the clinical findings, the patient’s age, underlying conditions, and possible preliminary laboratory studies.

Elimination of the S. pneumoniae organism by prompt initiation of antibiotics is essential for reducing the morbidity and mortality of pneumococcal infection. Antibiotic administration should begin in the emergency department. To simplify selection of a treatment strategy, patients can be divided into three groups:

1. Bacteremia or sepsis is suggested on the basis of clinical findings; however, the organism has not been identified. The patient in this group is given broad-spectrum antibiotics initially, with the selection based on factors that include the most likely organism or organisms, the patient’s age (neonate, child, adult, or elder) and immune status, the presence of coexisting conditions, and local patterns of antibiotic resistance. The antibiotic regimen is changed to a narrower spectrum drug after positive identification of the organism and its sensitivities.

2. S. pneumoniae growth is reported from cultures of blood drawn (usually 1–2 days) previously. The treatment regimen for “occult bacteremia” is guided by the patient’s age, history, physical examination, general appearance, and ancillary tests. Often, the antibiotic selected on the initial visit for a localized infection (e.g., amoxicillin) is sufficient to treat the pneumococcal bacteremia subsequently identified by the laboratory. The patient should be reevaluated promptly. Repeated blood cultures should be obtained if the patient has not been taking an antibiotic. For well-appearing children a 7- to 10-day course on an appropriate oral antibiotic is reasonable. The decision to admit a child for inpatient care is based on the findings at the time of reevaluation.60
3. Bacteremia or sepsis is suggested, and *S. pneumoniae* is identified from a site of local infection, such as a Gram’s stain of sputum. The antibiotic regimen is focused narrowly.

The adult patient with laboratory-proven pneumococcal pneumonia may be treated with penicillin G if susceptibility has been documented: 2 to 4 million units every 4 hours IV if local penicillin resistance patterns are still low. Meningitis is treated with 4 million units of penicillin G every 4 hours. In children, the dosage for meningitis is 250,000 units/kg per 24 hours in divided doses every 4 hours IV up to a maximum of 20 million units.

As of 2006, the *S. pneumoniae* susceptible to penicillin in the United States ranged from 50.9% in the Southeast to 73.8% in the Northwest. Unless penicillin susceptibility has been documented in a patient’s isolate, treatment should begin with either ceftriaxone (1–2 g IV every 12–24 hr; 50–100 mg/kg/day in children) or cefepime (1–2 g IV every 12 hr; 50 mg/kg every 8 hr in children). When meningitis is present, the higher doses should be given. In areas where ceftriaxone resistance has emerged, the addition of vancomycin (1 g IV every 12 hr; 40 mg/kg/day divided every 6–8 hr in children) should be considered. An infectious disease consultant may be able to assist with antibiotic selection based on local resistance patterns.

IM ceftriaxone is commonly administered to children with suggested occult bacteremia who are treated as outpatients while blood culture results are pending. Ceftriaxone (initial dose of 50–100 mg/kg IM or IV, followed by daily dosage of 100 mg/kg in divided doses every 12 hr, up to a maximum of 4 g) and cefotaxime (200 mg/kg/day in divided doses every 6 hr IV, up to a maximum of 12 g) offer the advantage of being excellent antibiotics for *N. meningitidis* and *H. influenzae*. Alternative initial treatment of pneumococcal in penicillin- or cephalosporin-allergic patients includes vancomycin, imipenem, and chloramphenicol. Chloramphenicol has the associated risk of toxicity and interaction with anticonvulsant medications.

The patient with pneumococcal pneumonia may not have an obvious response to treatment for the first 24 to 48 hours of therapy. This may be attributed to the normal course of the disease, an incorrect diagnosis, underlying illness, or an antibiotic regimen that does not treat the infection sufficiently.

**Disposition**

Disposition of the patient depends on three factors: the patient’s age, overall clinical condition, and the presence of coexisting illnesses. Toxie-appearing patients of any age should be promptly treated with antibiotics and admitted to the hospital. Patients with underlying or coexisting conditions and those with an unclear course of illness should also be admitted.

Children who are afebrile and appear well at the time of the initial examination are unlikely to have serious sequela develop. A large randomized, controlled trial involving 37,868 infants showed that invasive pneumococcal disease is rare in children who have received the heptavalent pneumococcal vaccine. Children were observed for 3 years. There was only one case of bacteremic pneumonia in a patient who had received all four doses of vaccine and two cases in children who had received one dose; one of these children had developed acute myelogenous leukemia after entering the study and was receiving immunosuppressive chemotherapy. It is important to note that the heptavalent vaccine contains serotypes responsible for only approximately 85% of pneumococcal disease in infants and children. The decision to treat a febrile child with antibiotics and discharge should be based on clinical findings, medical history, ability of the parents to follow the discharge instructions, and availability of timely follow-up.

**Vaccination**

The pneumococcal vaccine is effective in preventing infection; the currently available 23-valent vaccine contains the purified polysaccharide antigens of the serotypes that cause 85 to 90% of pneumococcal infections in the United States. Although the overall protective efficacy of the vaccine is only 56 to 57%, it is safe, inexpensive, and of substantial value for well-defined groups at risk. Unfortunately, the 23-valent pneumococcal vaccine has limited immunogenicity in children younger than 2 years. The heptavalent conjugate vaccine links the polysaccharide to proteins, resulting in an improved immunogenic response in children younger than 2 years.

The CDC recommendations for the use of the 23-valent vaccine are given in Box 127-3.

The CDC and AAP recommendations for the use of the heptavalent vaccine are listed in Box 127-4.

The Immunization Practices Advisory Committee on pneumococcal vaccine and the AAP recommend that revaccination be strongly considered at 2 to 6 years of age or older for people who are most likely to have a rapid decline of pneumococcal antibodies (e.g., patients with renal failure, transplant recipients, and patients with nephrotic syndrome) and for those at risk for fatal infection (e.g., asplenic patients). Children 10 years of age or younger with nephrotic syndrome, sickle cell anemia, or asplenia should be considered for revaccination after 3 to 5 years. Other preventive measures for pneumococcal include passive immunization with immunoglobulins for patients with congenital or acquired immunodeficiency.

**BOX 127-4 CDC RECOMMENDATIONS FOR THE USE OF THE 23-VALENT PNEUMOCOCCAL VACCINE**

- Immunocompetent adults with chronic illnesses
- Cardiovascular or pulmonary disease
- Diabetes mellitus
- Alcoholism or cirrhosis
- CSF leaks
- Those 65 years of age or older

**Immunocompromised adults including those with:**

- Splenic dysfunction or asplenia
- Hodgkin’s disease, lymphoma, or leukemia
- Multiple myeloma
- Chronic renal failure or nephrotic syndrome
- Alcoholism
- Organ transplantation associated with immunosuppression
- Adults and children older than 2 years with asymptomatic HIV infections
- Children older than 2 years with chronic illness
- Anatomic or functional asplenia (including sickle cell disease)
- Nephrotic syndrome
- CSF leak

**Other conditions associated with immunosuppression**

- Persons living in special environments or social settings with an identified increased risk (e.g., certain Native American populations)
- The vaccine is not indicated for children having only recurrent upper respiratory tract disease, such as otitis media and sinusitis

CDC, Centers for Disease Control and Prevention; CSF, cerebrospinal fluid; HIV, human immunodeficiency virus.
 CDC AND AAP RECOMMENDATIONS FOR THE USE OF THE 7-VALENT VACCINE

All children ages 2–23 months at 2, 4, 6, and 12–15 months
Children ages 24–59 months who are at high risk of pneumococcal disease, including those with:
Sickle cell disease
HIV infection
Other immunocompromising medical conditions
This should be followed by the 23-valent vaccine
2 months after the heptavalent vaccine is given
Consider for all children ages 24–59 months with priority given to the following:
Those ages 24–35 months
Alaskan natives, Native Americans, and African Americans
Children who attend daycare

AAP, American Academy of Pediatrics; CDC, Centers for Disease Control and Prevention; HIV, human immunodeficiency virus.

Box 127-5

MENINGOCOCCEMIA

Perspective

Background

Few clinical situations in emergency medicine produce greater anxiety in the physician than meningococcal infection. Virtually all experienced emergency physicians have had a patient who appeared relatively well on initial presentation, only to be moribund and in critical condition with fulminant infection several hours later.

“Epidemic cerebrospinal fever” was initially described in 1805 by Vieusseaux in Geneva. Weichselbaum identified the causative bacterial agent in 1887. Throughout the 19th and first half of the 20th centuries, epidemics occurred periodically in most regions of the world. “Serum therapy” was introduced in France in 1907 and in the United States in 1913 as the first specific treatment of meningococcal disease. The introduction of sulfonamide therapy in 1937 replaced serotherapy and dramatically improved the outcome of meningococcal infection. Sulfonamide prophylaxis was also effective at eradicating the carrier state and was used to prevent the epidemics that occurred in military barracks. Not surprisingly, in the 1940s sulfonamide resistance began to emerge. In 1963, an outbreak of resistant meningococcal disease occurred in the United States, which spurred efforts to develop a vaccine for this devastating infection. Subsequent worldwide resistance has resulted in continued efforts to develop safe and effective vaccines. Although grouping is important for tracking the disease, all groups are capable of causing the same spectrum of clinical disease.

The incidence of meningococcal disease peaks in the winter and falls in the summer. Superimposed on this annual variation are cyclical peaks of disease every 5 to 15 years. Approximately every 10 years massive outbreaks of serogroup A occur in sub-Saharan Africa (the “meningitis belt”). The last outbreak was in 2007. During nonepidemic periods, children younger than 5 years have the highest incidence of infection. During epidemics, the incidence increases among children ages 5 to 9, an observation that may be of value in predicting the beginning of an epidemic. Crowded living conditions increase the risk of spread of meningococcal disease. The incidence of disease and the carrier state are several times higher among military recruits in the first few weeks of service than in the general public. This is also true of college freshmen, particularly those living in dormitories or residence halls. Other risk factors for developing invasive meningococcal disease include close contact with an infected patient, complement deficiency, properdin deficiency, asplenia, chronic alcohol abuse, active and passive smoking, corticosteroid use, and recent respiratory illness.

The overall mortality rate of meningococcal disease is 10% in the United States. Septicemia without meningitis carries a much higher mortality rate (up to 70%) than meningitis alone (2–10%).

Principles of Disease

Etiology

Meningococcal disease is caused by N. meningitidis, a fastidious, aerobic, gram-negative diplococcus. N. meningitidis is an encapsulated organism classified into at least 13 serogroups on the basis of the capsular polysaccharides.

Pathophysiology

N. meningitidis attaches to nonciliated epithelial cells in the nasopharynx using a number of adhesion factors. Once attached, it may either remain on the epithelial surface, causing an asymptomatic carrier state, or produce mild symptoms of an upper respiratory tract infection. In certain patients the bacteria enter the bloodstream and cause symptoms and signs of localized infection, bacteremia, sepsis, or fulminant infection. The precise host and microorganism characteristics that determine whether clinical disease develops are not fully understood, but the presence of bacteriocidal antibodies is
protective. Complement deficiency may play a role in a host’s inability to fight this infection. The capsule is required for *N. meningitidis* to adhere to epithelium, but only unencapsulated meningococci enter epithelial cells; capsular biosynthesis has been shown to stop as the bacteria enters the epithelial cell.68

The release of lipooligosaccharide and endotoxin by autolysis of the *N. meningitidis* cell is the initial event in the development of meningococcal sepsis. The exogenous mediators appear to stimulate the release of endogenous mediators, including tumor necrosis factor, interleukin-1, and the host’s complement system. All of the major pathophysiologic events of meningococcal sepsis are caused by the host’s inflammatory response to the organism. The complement-activating products and other chemical mediators cause functional and histologic damage to the microvasculature, resulting in increased vascular permeability, pathologic vasoconstriction and vasodilation, loss of thromboresistance, DIC, and profound myocardial dysfunction.70-72

After exposure to *N. meningitidis*, protective antibodies develop. Immunity in children is conferred initially by maternal antibodies that pass through the placenta and later by the development of antibodies after exposure to the bacteria. In children, the incidence of meningococcal disease is inversely proportional to the levels of antibodies against *N. meningitidis*.71

**Clinical Features**

**Symptoms and Signs**

The clinical presentation of meningococcemia ranges from a mild febrile illness to fulminant disease progressing to death within hours. Most patients have fever on presentation. Other initial complaints include headache, irritability, lethargy, myalgias, emesis, diarrhea, cough, and rhinorrhea. Only 60% of patients have the classic signs of meningococcemia: fever and petechiae or purpura. These patients can rapidly progress to purpura fulminans, with hypotension, adrenal hemorrhage, and multiorgan failure.70 The following categories detail the five patterns of presentation:

1. **Occult Bacteremia:** This condition arises as a febrile illness in which the only direct indication of meningococcal meningitis is a positive blood culture with results available most often 24 to 48 hours after the clinical evaluation. In its mildest form, meningococcal bacteremia cannot clinically be distinguished from more benign febrile illnesses. Initial diagnoses in these patients include common childhood infections such as otitis media, acute viral upper respiratory infections, and gastroenteritis. For some patients the illness resolves after treatment with an oral regimen of antibiotics; others experience spontaneous resolution without antibiotic treatment.68 *N. meningitidis* accounts for 1 to 5% of occult bacteremia cases, but these patients are much more likely to develop meningitis (up to 58%) than those with *S. pneumoniae*. Also, despite the total absence of clinical clues to meningococcal infection at initial presentation, some untreated patients subsequently deteriorate rapidly.73

2. **Meningococcal Meningitis:** Patients with meningococcal meningitis may present similarly to patients with meningitis of other origins with headache, photophobia, vomiting, fever, and signs of meningeal inflammation. This classic constellation of symptoms and signs is present in less than half of the patients. Infants and small children may present with fever, irritability, and vomiting as the only complaints. More than half of patients with meningococcal meningitis have rash on presentation, and 20% present with seizures.73

Patients with meningococcal meningitis have a less abrupt onset of symptoms (usually over 24 hours) and a better prognosis than those with meningococcemia without clinical signs of meningitis.

3. **Meningococcal Septicemia:** Patients with meningococcal septicemia present with lethargy, poor tissue perfusion, cyanosis, and hyperventilation or hyperventilation. Hemorrhagic skin lesions are present in 28 to 77% of patients, but a macular or maculopapular rash may also occur and be mistaken for a variety of viral exanthems. Petechiae generally appear on the extremities and may appear under pressure points such as the elastic bands of socks and underwear. They may progress to involve almost any body surface, including the mucosa and sclera, but typically spare the palms, soles, and head. Macular lesions may progress to purpura and ecchymoses in fulminant meningococcemia. The purpurae are not a coalescence of petechiae but a distinct entity that more specifically characterizes meningococcemia. Purpura fulminans, the most dreaded and advanced form of meningococcal septicemia, occurs most often in children and is usually associated with DIC. This condition is characterized by rapidly spreading ecchymoses and gangrene of the extremities. Evidence of mucosal and gastrointestinal bleeding as well as oozing from IV sites may be noted on examination. Clinical signs of meningitis and CSF pleocytosis may not be present, even when diplococci are isolated from the CSF. This is probably because the systemic progression of the disease is so rapid that it precludes a host meningeal inflammatory response to the organism in the CSF. Shock results from both intravascular volume loss and congestive heart failure, probably related to myocarditis. Renal failure, coma, and bilateral adrenal hemorrhage often occur.68,73,74

4. **Fever and a Nonblanching Rash:** Up to 30% of patients present without signs of meningitis or septicemia. They are typically admitted for fever and a nonblanching rash and no other specific findings. If untreated, they can develop meningitis or fulminant septicemia and shock.68

5. **Chronic Meningococcemia:** This syndrome is characterized by fever, rash, and arthritis in conjunction with a positive blood culture for *N. meningitidis*. Headache and upper respiratory symptoms are often present. This is the rarest form of meningococcal disease, accounting for 1 to 2% of cases. It may progress to meningitis, endocarditis, or fulminant meningococcemia regardless of treatment.68

**Complications**

The most common complication of meningococcemia is myocarditis with congestive heart failure or conduction abnormalities. Many of the inflammatory mediators released during sepsis cause myocardial dysfunction, and the severity of sepsis is related to the degree of impairment of myocardial contractility. The acidosis, hypoglycemia, hypokalemia, hypocalcemia, hypophosphatemia, and hypoxia that accompany meningococcemia also contribute to the myocardial dysfunction. Patients may become unresponsive to positive inotropic medications.71

Acute respiratory failure occurs due to capillary leak in the patient who requires volume resuscitation. It is also likely that intrapulmonary DIC contributes to the pulmonary edema, and patients frequently require mechanical ventilation. Renal failure is common secondary to impaired renal perfusion; acute tubular necrosis may develop. If meningitis accompanies meningococcemia, focal neurologic signs as well as seizures may occur but are less common than with pneumococcal meningitis. Vasculitis in severe cases of meningococcal septicemia
may result in skin lesions that necessitate plastic surgery and loss of digits or limbs resulting from gangrene. Purulent or immune complex arthritis and pericarditis with tamponade may also occur.69,71,74

Poor prognostic indicators in meningococcemia include seizures on presentation, hypothermia, hyperyperpyrexia, a total peripheral WBC count of less than 500/mm³, a platelet count of less than 100,000/mm³, metabolic acidosis (pH < 7.30), the development of purpura fulminans, the onset of petechiae within 12 hours of admission, absence of meningitis, the presence of shock, a low sedimentation rate, and extremes of age. In one study, all patients who developed organ system failure had one or more of the following at the time of initial presentation: circulatory insufficiency (hypotension or shock), peripheral WBC count less than 10,000 cells/mm³, or a coagulopathy. Herpes labialis occurs in 5 to 20% of patients with meningococcal disease.73,75

Diagnostic Strategies

The tentative diagnosis of meningococcemia is based on clinical findings and confirmed by the isolation of *N. meningitidis* from blood cultures or any other usually sterile site such as CSF or synovial, pleural, or pericardial fluid. Ideally, blood cultures should be obtained before the administration of antibiotics unless this unduly delays the patient’s treatment. Blood cultures are positive in approximately 50 to 80% of cases. A lumbar puncture should only be performed in stable patients without evidence of DIC. The CSF shows either gram-negative diplococci on Gram’s stain or a positive culture in about 80 to 90% of cases. Even patients without clinical signs of meningitis frequently have the organism grown from the CSF. Gram’s stain of petechial scrapings may show gram-negative diplococci in up to 70% of cases, and, rarely, the organism can be seen in the peripheral blood buffy coat. Highly specific antigen tests for CSF are available but have a high false-negative rate. PCR of the buffy coat or CSF is more sensitive and specific than any of the preceding tests and is not affected by prior antibiotic therapy.68,74-76

Ancillary laboratory tests are of little value in establishing a specific diagnosis of meningococcal sepsis but may be useful in ruling out other disease, determining prognosis, and monitoring complications. The WBC count may be high, low, or normal, but a bandemia is typically present. The symptoms and signs of CNS infection may be nonspecific in the infant and child younger than 2 years. If meningitis is present, the CSF opening pressure is usually elevated, the protein level remains low in the United States but has been reported in Spain and the United Kingdom.68,77 The emergency physician should keep informed of any emerging resistance patterns in the practice area.78 Although it is appropriate first-line therapy, penicillin is rarely given as the initial agent in patients with suggested meningococcal sepsis or meningitis. Ceftriaxone (initial dose of 100 mg/kg IV, followed by daily dosage of 100 mg/kg in divided doses every 12 hours up to a maximum of 4 g) or cefotaxime (100 mg/kg/day IV in divided doses every 6 hours up to a maximum of 12 g) are appropriate initial antibiotics as well. The cephalosporins offer the advantages of safety, rapid onset of action, and excellent coverage for *S. pneumoniae* and *H. influenzae*. Chloramphenicol (50–100 mg/kg/day divided every 6 hours to a maximum of 4 g/day) should be considered in penicillin- and cephalosporin-allergic patients.68 Ceftriaxone IM is commonly administered to children with suspected bacteremia who are treated as outpatients while culture results are pending. Several reports have demonstrated the efficacy of ceftriaxone (80–100 mg/kg IV) in a single daily dose; however,

Differential Considerations

It is difficult to distinguish the clinical signs of meningococcemia from those of bacteremia caused by *S. pneumoniae*, other streptococcal groups, *H. influenzae*, and *Neisseria gonorrhoeae*. The differential diagnosis of meningococcemia also includes viral exanthems, Rocky Mountain spotted fever, typhus, typhoid fever, endocarditis, vasculitis syndromes (polyarteritis nodosa and Henoch-Schönlein purpura), toxic shock syndrome, acute rheumatic fever, drug reactions, idiopathic thrombocytopenic purpura, and thrombotic thrombocytopenic purpura.75

In one study of 184 children hospitalized with fever and petechiae, 24 (11%) had proven *N. meningitidis*. The remainder showed evidence of viral or other organisms. These data were acquired prior to the initiation of a vaccination program.77

Management

Acute Treatment

Morbidity and mortality in meningococcemia are reduced with prompt recognition and immediate initiation of antibiotic therapy. Delays in initiating therapy for the completion of diagnostic studies or admission to an inpatient unit should be avoided. To simplify selection of a treatment strategy, patients can be divided into three general groups:

1. **Bacteremia or sepsis is suggested on the basis of clinical findings; however, the organism has not been identified.** These patients should receive broad-spectrum antibiotics, with selection based on factors that include the most likely organism or organisms, the patient’s age and immune status, the presence of coexisting disorders, and local patterns of antibiotic resistance. A narrower spectrum agent is selected after positive identification of the organism and its sensitivities.

2. **N. meningitidis growth is reported from prior blood cultures.** The treatment regimen for occult bacteremia is guided by the patient’s age, history, physical examination, general appearance, and ancillary tests. The antibiotic selected at the time of the initial visit may be sufficient to treat the meningococcal bacteremia subsequently identified by the laboratory. The decision to hospitalize the patient is based on the findings at the time of reevaluation and the risk of sequelae. Regardless of the patient’s clinical appearance, most physicians would redraw blood for cultures, consider lumbar puncture, and admit the patient to the hospital until results of repeated cultures are obtained.

3. **Bacteremia or sepsis is suggested and *N. meningitidis* is identified.** The antibiotic regimen is focused narrowly.

The standard antibiotic regimen for laboratory-proven meningococcemia is penicillin G, 4 million units every 4 hours IV for adults, and penicillin, 250,000 to 300,000 units/kg/day in divided doses every 4 hours IV for children, up to a maximum of 20 million units. Penicillin resistance in *N. meningitidis* remains low in the United States but has been reported in Spain and the United Kingdom.68,77

The decision to hospitalize the patient is based on the findings at the time of reevaluation and the risk of sequelae. Regardless of the patient’s clinical appearance, most physicians would redraw blood for cultures, consider lumbar puncture, and admit the patient to the hospital until results of repeated cultures are obtained.

Although it is appropriate first-line therapy, penicillin is rarely given as the initial agent in patients with suggested meningococcal sepsis or meningitis. Ceftriaxone (initial dose of 100 mg/kg IV, followed by daily dosage of 100 mg/kg in divided doses every 12 hours up to a maximum of 4 g) or cefotaxime (100 mg/kg/day IV in divided doses every 6 hours up to a maximum of 12 g) are appropriate initial antibiotics as well. The cephalosporins offer the advantages of safety, rapid onset of action, and excellent coverage for *S. pneumoniae* and *H. influenzae*. Chloramphenicol (50–100 mg/kg/day divided every 6 hours to a maximum of 4 g/day) should be considered in penicillin- and cephalosporin-allergic patients.68 Ceftriaxone IM is commonly administered to children with suspected bacteremia who are treated as outpatients while culture results are pending. Several reports have demonstrated the efficacy of ceftriaxone (80–100 mg/kg IV) in a single daily dose; however,
twice-daily dosing remains the standard recommendation at this time. In addition to the obvious advantage of extended dosing intervals, ceftriaxone-treated patients have a more rapid sterilization of the CSF and a lower incidence of hearing loss than conventionally treated patients.

Patients with fulminant meningococcemia require prompt airway management, IV fluid resuscitation, and vasopressor support. Fluid requirements may be high because of third spacing of fluid, and in the setting of frequent myocardial dysfunction, intensive cardiovascular monitoring is required. Electrolyte and acid-base abnormalities should be corrected. If the patient is oliguric or anuric, hemodialysis may be necessary to correct these abnormalities. Fresh frozen plasma should be considered for patients with bleeding complications.68,79

The role of steroids for the treatment of meningococcemia without meningitis remains controversial. Although corticosteroids were once widely recommended for the treatment of the adrenal insufficiency associated with fulminant meningococcemia, more recent studies demonstrate that adrenal function is not impaired in all patients. If a patient has persistent shock despite vigorous fluid resuscitation and vasopressor therapy, glucocorticoid therapy may be considered and adrenal function tested.80

The use of corticosteroids in patients with bacterial meningitis is currently recommended for adults and children, but not neonates. The most recent clinical data show that corticosteroid administration prior to antibiotic administration decreases mortality rates in adults and long-term neurologic sequelae in adults and children. Dexamethasone (0.4–0.6 mg/kg/day every 6 hours for 4 days) should be given to patients with bacterial meningitis. The first dose should be given prior to the first dose of antibiotics if possible.81

Plasmapheresis, blood exchange, and extracorporeal membrane oxygenation have all been described with favorable outcome, but data are limited.73

Disposition
All patients with possible or confirmed meningococcemia should be admitted to the hospital, preferably to an ICU because these patients can decompensate rapidly and without warning.76 A possible exception is the child who has culture-proven *N. meningitidis* and has been taking appropriate antibiotics as an outpatient. This child should have a lumbar puncture to determine CSF involvement if one was not performed at the initial evaluation. Antibiotics should be continued as an inpatient, but an ICU may not be necessary if the child appears well.

Antibiotic Prophylaxis and Vaccination
Patients with meningococcemia should be placed in respiratory isolation for at least 24 hours. Close contacts should receive antibiotic prophylaxis. Household, nursery school, and daycare center contacts should receive prophylaxis promptly. Intimate contacts and health care workers with intimate exposure (e.g., mouth-to-mouth resuscitation, intubation, or suctioning) should receive rifampin, 10 mg/kg (up to 600 mg) orally every 12 hours for four doses. The dose for infants younger than 1 month is 5 mg/kg. Patients should be warned that rifampin discolors the urine and secretions; contact lenses should be removed to avoid permanent staining. Ceftriaxone IM (125 mg for children younger than 15 years and 250 mg for those older than 12) is effective against group A strains. This is an alternative for pregnant women and for people in whom compliance with an oral regimen cannot be ensured. Ciprofloxacin (500 mg orally) is another alternative for adults.68,70

Meningococcal vaccine should be considered as an adjunct to prophylaxis in epidemics and for close contacts in sporadic cases if one of the serotypes contained in the vaccine is identified as the causative agent. The currently available vaccine is a quadrivalent vaccine containing purified capsular polysaccharides for groups A, C, Y, and W-135. Unfortunately, the polysaccharides other than A are poorly immunogenic for children younger than 2 years. In addition, no vaccine exists for group B, a serogroup that causes a significant portion of meningococcal infection in the United States. The quadrivalent vaccine is not recommended for routine use but should be administered to children 2 years of age and older in high-risk groups, such as those with functional or anatomic asplenia, and those with terminal complement deficiency. In 2000, the CDC Advisory Committee on Immunization Practice (ACIP) recommended that college students, especially those living in dormitories, and their parents be advised of the risks of meningococcal disease and be offered vaccination. In August 2007, the ACIP recommended that all persons aged 11 to 18 years receive the vaccine. The vaccine is currently administered to U.S. military recruits. Consideration should be given to vaccinating people traveling to endemic areas of the world such as sub-Saharan Africa.69,70,82

TOXIC SHOCK SYNDROME

Perspective

Background

Toxic shock syndrome (TSS) is a toxin-mediated systemic inflammatory response syndrome that was first described by Todd and colleagues in 1978. They reported a series of seven children from ages 8 to 17 years who had high fever, rash, headache, confusion, conjunctival injection, edema, vomiting, diarrhea, renal failure, hepatic dysfunction, DIC, and shock. *S. aureus* was cultured from various body sites but not the blood in five of the seven cases.83,84

The disease gained notoriety in the early 1980s when many cases were reported in association with tampon use in young, healthy menstruating women. The term toxic shock syndrome was coined to describe the constellation of signs and symptoms. Investigators noted positive vaginal cultures for *S. aureus*, recurrence of illness during subsequent menses, and the value of antistaphylococcal antibiotics in preventing recurrences. In response to the growing concern about TSS, changes were made to reduce the absorbency and composition of tampons. Nonmenstrual cases were also recognized in both men and women as a result of a variety of predisposing conditions, and a case definition was published in 1982 (Box 127-6).85-88

In the late 1980s, several reports described group A *Streptococcus* (GAS) infection associated with shock and multisystem organ failure. This has been called *streptococcal toxic shock syndrome* (strept TSS) because it shares so many features with staphyloccocal TSS.85,86 Box 127-7 shows the case definition for strep TSS.89

Epidemiology

The peak incidence of TSS occurred in 1980, when 890 cases were reported, 91% of which were associated with tampon use. Since then, the reduction in cases of the menstrual form of TSS has followed an active effort to decrease tampon absorbency and change their composition.90 Menstruation remains the most common setting for TSS, but nonmenstrual TSS accounts for just under half of the reported cases. TSS has also been reported in association with barrier contraceptives and...
**BOX 127-6**  
**Case Definition of Toxic Shock Syndrome (Revised)**

- **Fever:** Temperature ≥ 38.9°C (102°F)  
- **Rash:** Diffuse macular erythroderma  
- **Desquamation:** 1–2 weeks after onset of illness, particularly of palms and soles  
- **Hypotension:** Systolic blood pressure ≤ 90 mm Hg for adults or below fifth percentile by age for children less than 16 years of age, orthostatic drop in diastolic blood pressure ≥ 15 mm Hg from lying to sitting, orthostatic syncope, or orthostatic dizziness  
- **Multisystem involvement:** three or more of the following:  
  - **Gastrointestinal:** Vomiting or diarrhea at onset of illness  
  - **Muscular:** Severe myalgia or creatine phosphokinase level at least twice the upper limit of normal for laboratory  
  - **Mucous membrane:** Vaginal, oropharyngeal, or conjunctival hyperemia  
  - **Renal:** BUN or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria (≥ 5 leukocytes/hpf) in the absence of urinary tract infection  
  - **Hepatic:** Total bilirubin, AST, and ALT at least twice the upper limit of normal for laboratory  
  - **Hematologic:** Platelets ≤ 100,000/mm³  
  - **CNS:** Disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent  
- **Negative results on the following tests,** if obtained:  
  - Blood, throat, or CSF cultures (blood culture may be positive for *Staphylococcus aureus*)  
  - Rise in titer to Rocky Mountain spotted fever, leptospirosis, or rubeola

ALT, serum alanine aminotransferase; AST, serum aspartate aminotransferase; BUN, blood urea nitrogen; CNS, central nervous system; CSF, cerebrospinal fluid.

**BOX 127-7**  
**Case Definition for Streptococcal Toxic Shock Syndrome**

- **Hypotension:** Systolic blood pressure ≤ 90 mm Hg for adults or below fifth percentile by age for children younger than 16 years  
- **Multisystem involvement:** two or more of the following:  
  - **Renal:** Creatinine > 2 mg/dl (177 µmol/L) for adults or more than twice the upper limit of normal for age or more than twofold elevation over baseline for patients with preexisting renal disease  
  - **Hematologic:** Platelets ≤ 100,000/mm³ or DIC defined as prolonged clotting times, low fibrinogen level, and the presence of FDPs  
  - **Hepatic:** Total bilirubin, AST, and ALT at least twice the upper limit of normal for laboratory, or a twofold increase in patients with preexisting liver disease  
  - **Acute respiratory distress syndrome:** Acute onset of pulmonary infiltrates and hypoxemia in the absence of cardiac failure or by evidence of diffuse capillary leak manifested by acute onset of generalized edema, or pleural or peritoneal effusions with hypoalbuminemia  
- **Generalized erythematous maculopapular rash** that may desquamate  
- **Soft tissue necrosis,** including necrotizing fasciitis, myositis, or gangrene  
- **Laboratory criteria for diagnosis:** isolation of GAS

**Case Classification**

- **Probable:** A case meets the clinical case definition in the absence of another identified cause for the illness and with isolation of GAS from a nonsterile site.
- **Confirmed:** A case meets the clinical case definition with isolation of GAS from a normally sterile site (e.g., CSF or joint, pleural, or pericardial fluid).

ALT, serum alanine aminotransferase; AST, serum aspartate aminotransferase; CF, cerebrospinal fluid; DIC, disseminated intravascular coagulation; GAS, group A Streptococcus.

**Principles of Disease**

**Etiology**

Streptococcal TSS is caused by colonization or infection with toxigenic strains of *Streptococcus aureus*. This strain produces toxic shock syndrome toxin-1 (TSST-1). *S. aureus* has been detected in virtually all cases of both forms of the illness. *S. aureus* has been isolated from the vagina or cervix in 98% of women with menstrual TSS, compared with a colonization rate of less than 10% of unaffected women. Because the organism is often not invasive, the blood cultures are often negative. Streptococcal TSS is caused by invasive infection with toxigenic strains of GAS.

**Pathophysiology**

The shock and multiorgan dysfunction associated with TSS are caused by the effects of various exotoxins produced by *S. aureus* and GAS. *S. aureus* produces TSST-1 and enterotoxin B. TSST-1 is identified in more than 90% of menstrual cases and 60% of nonmenstrual cases. Other toxins may play a role in nonmenstrual TSS. Antibodies to these toxins are protective against disease. GAS produces streptococcal pyrogenic exotoxins A (SPEA) and B (SPEB). These exotoxins are...
absorbed into the bloodstream through inflamed or traumatized mucous membranes or from areas of focal infection. Absorbed toxins act as superantigens, inducing mononuclear cells to synthesize and release cytokines, tumor necrosis factor $\alpha$, and interleukins, which begin the cascade of systemic vasculitis and the multisystem manifestations of the disease. Host immune factors are important in the pathogenesis of TSS. GAS is an invasive organism, and circulating GAS organisms induce the production of tumor necrosis factor $\alpha$ and other cytokines by mononuclear cells.84–87,93

Clinical Features

Symptoms and Signs

The clinical presentations of streptococcal TSS and staphylococcal TSS are similar. The primary difference is that an identifiable infectious source is virtually always present with streptococcal TSS, and colonization alone may be the source in staphylococcal TSS.

Patients may have fever, chills, nausea, vomiting, watery diarrhea, headache, myalgias, and pharyngitis. This prodromal illness may last for 2 to 3 days before progression to frank sepsis and organ dysfunction. Others patients may become abruptly symptomatic within hours. Rapid progression is more typical of streptococcal TSS. Patients may complain of pain at a site of infection more often with streptococcal TSS. Risk factors for TSS are listed in Box 127-8.

The fever is usually high and abrupt in onset, although septic patients may have hypothermia on presentation. The classic rash is a nonpruritic, diffuse, blanching, macular erythema. It develops over the first few days of the illness and initially may be faint, evanescent, and mistaken for the flush associated with a fever. The rash is usually diffuse but may be localized to the trunk, extremities, or perineum. After about a week, a fine flaking desquamation occurs on the face, trunk, and extremities, followed by full-thickness peeling of the palms, soles, and fingers. This classic rash progression is much more common in staphylococcal TSS and is present in less than 10% of patients with streptococcal TSS.93

The patient’s mental status is frequently abnormal, out of proportion to the degree of hypotension. Confusion, somnolence, agitation, and combative ness are present in 55% of patients with streptococcal TSS and in even more patients with staphylococcal TSS.84,85,93

Other findings on physical examination may include pharyngeal and conjunctival erythema, strawberry tongue, and periph-

Complications

Complications of TSS include acute respiratory distress syndrome, shock, gangrene, DIC, renal failure, and a constellation of neuropsychiatric symptoms. Less common findings in staphylococcal TSS include rhabdomyolysis, seizures, pancreatitis, pericarditis, and cardiomyopathy. Women with the menstrual form of TSS may experience one or more recurrent episodes; recurrences of the nonmenstrual form are rare. Complication rates are higher with streptococcal TSS. Rhabdomyolysis occurs in up to 63% of patients with streptococcal TSS and is usually related to the underlying soft tissue infection.84–87

Diagnostic Strategies

The case definition for TSS does not require a positive culture for S. aureus but does for Streptococcus organisms. These case definitions (see Boxes 127-6 and 127-7) are useful to the clinician, but they are neither specific nor foolproof. Specific tests are not required to exclude other diseases, but if such tests are obtained, the results of these studies must be negative.

No specific laboratory changes are associated with TSS, but many abnormalities are common. Either leukocytosis or leukopenia can occur, but a marked bandemia is very common. Elevated creatinine levels and hemoglobinuria occur in most patients. Laboratory evidence of renal dysfunction occurs prior to hypotension in half of the patients. Hypoalbuminemia and life-threatening hypocalcemia are prominent initially and persist throughout the course of the disease. Other abnormalities include anemia, thrombocytopenia, hyperbilirubinemia, elevated transaminase levels, and sterile pyuria.84–87

Chest radiography may reveal evidence of acute respiratory distress syndrome or a pulmonary source of the organism. Plain radiographs of any infected skin or soft tissue site typically

NSAID, nonsteroidal anti-inflammatory drug.

**Box 127-8** Risk Factors for Toxic Shock Syndrome

- Use of superabsorbent tampons
- Postoperative wound infections
- Postpartum period
- Nasal packing
- Cancer
- Common bacterial infections
- Ethanol abuse
- Infection with influenza A
- Infection with varicella
- Diabetes mellitus
- Human immunodeficiency virus infection
- Chronic cardiac disease
- Chronic pulmonary disease
- Nonsteroidal anti-inflammatory use (may mask symptoms rather than be a risk factor)
show only soft tissue swelling but may reveal evidence of a retained foreign body or air in the soft tissue. It is important to note that a lack of air in the soft tissue does not rule out a necrotizing soft tissue infection.

An ECG may reveal evidence of ischemia, arrhythmias, and varying degrees of atroventricular block in association with sepsis.85 A blood gas analysis may indicate metabolic acidosis secondary to hypotension or hypoxia. A lumbar puncture should be performed in febrile patients with altered mental status to evaluate for meningitis. It is prudent to wait for the results of a coagulation profile in these patients before performing the lumbar puncture as DIC may be present at presentation. The CSF is normal in patients with TSS. Serologic tests for Rocky Mountain spotted fever and leptospirosis should be considered in endemic areas.85

Differential Considerations

The differential diagnosis includes any severe febrile illness with exanthema, associated with hypotension. Other diseases to consider include heat stroke, cellulitis, Kawasaki disease, staphylococcal scalded-skin syndrome, scarlet fever, drug reactions such as Stevens-Johnson syndrome, toxic epidermal necrolysis (TEN), Rocky Mountain spotted fever, Clostridial gas gangrene, leptospirosis, meningococemia, gram-negative sepsis, atypical measles, and viral illnesses.

Kawasaki disease occurs almost exclusively in children, usually does not progress to shock, lacks multisystem involvement, exhibits a protracted fever, and is associated with thrombocytosis later in its course. Staphylococcal scalded-skin syndrome arises with a desquamating rash acutely, whereas the desquamation of TSS occurs in the convalescent phase. Staphylococcal scalded-skin syndrome does not progress to shock, is not associated with multisystem illness, and lacks mucous membrane involvement. Scarlet fever differs in its clinical course by lack of shock and multisystem involvement, positive cultures for GAS, and a rise in the convalescent titer. Stevens-Johnson syndrome usually occurs after drug administration, has characteristic mucous membrane lesions, and lacks desquamation. TEN may be difficult to distinguish from TSS, as TEN patients are typically febrile, in shock, and can progress to multisystem failure. The desquamation of TEN occurs early in the course of the disease, and it usually occurs after administration of a drug. Rocky Mountain spotted fever occurs after a tick bite, has a distinctive rash, and is associated with a severe headache without an altered mental status or hypotension. Leptospirosis occurs in endemic areas and may be distinguished by positive serologic studies and cultures. The rash of meningococemia is characterized by petechiae and purpura occurring anywhere on the skin.84,85

Management

Patients with TSS should receive aggressive fluid resuscitation with crystalloids and may require up to 10 to 20 L/day. Supplemental oxygen should be provided to all septic patients regardless of initial pulse oximetry. This allows maximum tissue oxygenation and reduces acidosis. Patients should be placed in a monitored setting. Assisted ventilation may be necessary in patients with acute respiratory distress syndrome. Hyperbaric oxygen therapy has been studied as a potential treatment for TSS but without proven benefit.84,85

The source of bacteria, such as tampons, nasal packs, and other foreign bodies, must be removed. Prompt surgical consultation should be obtained to débride wounds. If specimens are sent for culture, the laboratory should be informed of the suggested diagnosis.

Patients who do not respond to fluid resuscitation require vasopressors such as dopamine, phenylephrine, norepinephrine, and epinephrine.

Antibiotics should be initiated early in the treatment of TSS, as the clinical presentation of the disease is similar whether the source is staphylococcal or streptococcal. For septic patients without an identified organism, broad-spectrum antibiotics should be administered. Although the penicillin-resistant penicillins (nafcillin, oxacillin) have been widely used in the treatment of TSS, most clinicians recommend clindamycin as a first-line agent. Clindamycin is a potent suppressor of bacterial toxin synthesis; it also facilitates phagocytosis of streptococci and has a longer postantibiotic effect than the β-lactams. The dose is 600 to 900 mg IV every 8 hours. (The pediatric dose is 20–40 mg/kg/day divided every 6–8 hr.) Clindamycin and azithromycin have also been shown to decrease monocyte synthesis of cytokines.84–87

Patients who do not respond to massive fluid resuscitation, antibiotics, and vasopressors should be considered for IV immunoglobulin treatment, especially if pulmonary edema develops and mechanical ventilation is required. Pooled immune globulin has high titers for antibodies to TSS-1 and other exotoxins, and significant improvement has been reported with its use. If used, the recommended dose is 2 g/kg on day 1 administered IV over several hours followed by 400 mg/kg/d for up to 5 days.84–87

The value of corticosteroids in TSS is still unresolved. They are not currently recommended for treating staphylococcal or streptococcal TSS but should be given to patients thought to have adrenal insufficiency related to underlying disease or chronic steroid use.84

Disposition

All patients thought to have TSS should be admitted to an ICU. Prompt surgical consultation should be obtained for patients with a wound source.85

CHAPTER 128  Viral Illnesses

Tenagne Haile-Mariam and Michael Alan Polis

Most viral infections manifest as benign, self-limited upper respiratory tract or gastrointestinal infections, and therapy most often is directed at control of symptoms. Exact identification of the causative virus usually is not required. With some viral diseases for which specific therapy or postexposure prophylaxis (PEP) is available, however, recognizing the disease and promptly instituting therapy or prevention can prevent permanent sequelae or death. Examples of how prompt recognition and therapy can change the outcome of potentially fatal viral illness are the early institution of acyclovir treatment for herpes simplex virus (HSV) encephalitis and the appropriate use of rabies vaccine and immunoglobulin for patients exposed to rabies.

CLASSIFICATION

Viruses were first distinguished from other microorganisms by their ability to pass through filters of small pore size. Initial classifications of viruses were based on their pathologic properties (e.g., enteroviruses) or epidemiologic features (e.g., arthropod-borne). More recently, classification has been based on the genetic relationships of the viruses. The components of the current classification are the type and structure of the viral nucleic acid, the type of symmetry of the virus capsid, and the presence or absence of an envelope (Table 128-1).

The genetic information of viruses is encoded in either DNA or RNA, which can be either single- or double-stranded and circular (closed-ended) or linear (open-ended). The genomes of the smallest viruses may code for only three or four proteins, whereas those of the largest viruses encode several hundred. A protein coat, called the capsid, is composed of a repeating series of protein subunits, called capsomeres. The viral nucleic acid and the surrounding protein coat are jointly referred to as the nucleocapsid. The use of repeating protein structures limits the shape of the capsid. All but the most complex viruses are either helically symmetrical or icosahedral. Finally, some virus nucleocapsids are surrounded by a lipid envelope acquired by the virus as it buds from the cell cytoplasm, nuclear membranes, or endoplasmic reticulum.

VIRAL IMMUNIZATIONS

Whereas treatment strategies against most bacterial diseases have focused on treating and eradicating bacteria from the host after disease has developed, the most successful strategies against viral diseases have concentrated on immunization. The history of immunization against viral diseases began in 1796, when Jenner injected pustular material from the lesions of cowpox into a child to prevent smallpox. The word vaccination is derived from vaccinia, referring to the skin reaction at the site of injection of such material for smallpox immunization, and originally meant “inoculation to render a person immune to smallpox.” Currently, the terms vaccination and immunization are used interchangeably to mean the administration of any vaccine. Immunization is a broader term that includes administering immunobiologics such as immunoglobulins.

Viral vaccines are suspensions of live, attenuated, or inactivated whole viruses or parts of viruses that are administered to induce immunity. Some vaccines, such as the surface antigen of hepatitis B, are highly defined; others, such as live, attenuated viruses, are complex. Immunoglobulin is an antibody preparation obtained from large pools of human blood plasma. It is given intramuscularly for passive immunization against measles and hepatitis A, and intravenously as replacement therapy for antibody-deficiency disorders. Specific immunoglobulins are preparations of monoclonal antibodies or are prepared from special donor plasma pools preselected for high antibody titers against specific antigens, such as those presented by the hepatitis B, varicella-zoster, or rabies viruses. None of the immunoglobulin preparations, when properly prepared, can transmit infectious viruses.

The modern era of immunization began in 1885, when Louis Pasteur and colleagues injected the first of 14 daily doses of rabbit spinal cord suspensions containing progressively inactivated rabies virus into 9-year-old Joseph Meister, who had been bitten by a rabid dog 2 days earlier. The introduction of the inactivated poliomyelitis vaccine (IPV) in 1955 and the attenuated live oral polio vaccine (OPV) in 1962 has virtually eliminated the threat of paralytic poliomyelitis in the United States and other developed countries.

Currently, a massive World Health Organization (WHO) campaign to eradicate polio worldwide is under way. As of 2007, in four countries (Pakistan, India, Afghanistan, and Nigeria), polio transmission has never been interrupted, and in several more countries in Asia and Africa, polio has re-emerged. Vaccines against measles, mumps, rubella, influenza, and hepatitis B have greatly reduced morbidity and mortality associated with these diseases. The worldwide eradication of smallpox in 1977 is a testament to the advances made against viral diseases.

Administration of an immunobiologic agent does not automatically confer adequate immunity. Some preparations require more than one dose to produce an adequate antibody response, or periodic boosters may be needed to maintain

Protection. The simultaneous administration of immunoglobulin with a live virus vaccine may result in diminished antibody response to the vaccine. Deviation from the recommended volume or number of doses of any vaccine is strongly discouraged. Significant problems also remain in developing countries that cannot afford vaccines or have problems delivering vaccines to their at-risk populations. Table 128-2 summarizes currently available viral vaccines, their indications, and recommended uses. Over the past several years, new vaccines have been developed against rotavirus, a major cause of diarrheal disease in young children worldwide; human papillomaviruses (HPVs), which are associated with urogenital cancers; and herpes zoster (shingles), which is a major cause of morbidity in mostly elderly patients.

#### Antiviral Chemotherapy

Because most viral illnesses are self-limited, treatment generally is targeted at ameliorating symptoms. The revolution in molecular biology has unlocked pathophysiologic mechanisms...

### Amantadine and Rimantadine

Amantadine (Symmetrel) and rimantadine (Flumadine) are effective in preventing and treating influenza A but have no activity against influenza B. They prevent or greatly reduce the uncoating of the viral RNA of influenza A after attachment and endocytosis by host cells. When initiated before exposure to influenza A, amantadine, 200 mg/day orally, is effective in preventing illness in 50 to 90% of subjects. When begun within 2 days after the onset of symptoms of influenza A, amantadine has reduced the duration of fever and systemic symptoms by 1 to 2 days. The drug generally is well tolerated, with the most common therapy-limiting toxicities being central nervous system (CNS) effects, such as nervousness, light-headedness, difficulty concentrating, insomnia, and decreased psychomotor performance. These reactions occur particularly in elderly patients who have impaired renal function; they should receive no more than 100 mg of amantadine daily. Rimantadine is mostly metabolized before renal excretion and is associated with a lower incidence of CNS toxicity than amantadine. Other side effects include nausea and loss of appetite. Overdose is associated with an anticholinergic syndrome.12

Prophylaxis with daily amantadine or rimantadine is indicated for the duration of the influenza season in persons at high risk for contracting influenza in whom the influenza vaccine is contraindicated. When influenza A is reported in a community, appropriate management is to administer the influenza vaccine and give amantadine for 2 weeks while antibody production is induced. Adults with acute onset of fever, cough, headache, and myalgia may be treated with 200 mg of amantadine, followed by 100 mg for 5 to 7 days.

Zanamivir and Oseltamivir

Zanamivir (Relenza) and oseltamivir (Flumadine) were approved in 1999 for the treatment of influenza A and B. Both medications act by inhibiting the activity of neuraminidase, an enzyme involved in the release of viral progeny from infected cells. They have been shown to decrease the duration of moderate or severe symptoms of influenza by approximately 1 day. Either medication should be started within 2 days of onset of symptoms if efficacy is to be expected. Zanamivir is administered by inhalation through a novel device (Diskhaler) and is approved for use in patients older than 12 years. The dose is 2 inhalations twice a day for 5 days. Most of the inhaled dose is deposited in the respiratory tract and cleared unchanged in the urine or stool. The most common side effect is bronchospasm in predisposed patients. Such patients should be given a fast-acting inhaled bronchodilator before receiving zanamivir.12,13

Oseltamivir is an oral medication approved for patients older than 18 years of age. The dose is 75 mg twice daily for 5 days. It is cleared by renal secretion, and reduction of the dose to 75 mg once daily is recommended for patients with a creatinine clearance of less than 30 mL/minute. Initial reports of influenza virus resistance to oseltamivir were followed by a rapid rise in such resistance in H1N1 strains in the United States during the 2008-2009 influenza season.13,14 This resistance was not seen in the H3N2 strain that was also circulating during the same season. This resulted in the CDC issuing interim treatment recommendations in December 2008. If treatment was based on the identification of the infecting virus, zanamivir was recommended as first-line treatment for H1N1 and oseltamivir for H3N2. If such data were not available to the treating physician, the CDC recommended that clinicians review local disease surveillance data to determine which subtype was more likely to be the offending agent and choose treatment accordingly.15 It is unclear if these new recommendations will change during subsequent influenza seasons.

Acyclovir

Acyclovir (Zovirax) is one of the drugs of choice for serious infections caused by HSV or varicella-zoster virus (VZV). Only 15 to 30% of the oral formulation is absorbed, so the intravenous form is required to treat HSV encephalitis, disseminated or ophthalmic zoster, or extensive HSV or VZV infection in the immunocompromised patient. Oral acyclovir has some use in treating primary HSV infections and in suppressing frequent recurrences of these infections.15 In general, the more immunocompromised the patient, the greater the likelihood that he or she will require intravenous acyclovir therapy. Acyclovir rarely is associated with gastrointestinal upset, reversible renal dysfunction, or encephalopathy. Acyclovir-resistant isolates have been found in immunocompromised patients receiving multiple courses of therapy for HSV and VZV infections. These isolates may be less virulent and may remain sensitive and respond to treatment with foscarnet.16,17

Famciclovir and Valacyclovir

Famciclovir (Famvir) and valacyclovir (Valtrex) are analogs of acyclovir that inhibit herpesvirus DNA synthesis.16,19 They are much more bioavailable than acyclovir and can be given less frequently. Both are available only as oral formulations.

Ganciclovir

Ganciclovir (Cytovene) is used to treat life- or sight-threatening CMV infections in immunocompromised patients.20 Patients with acquired immunodeficiency syndrome (AIDS) and CMV colitis or esophagitis may also improve with ganciclovir. Some CMV isolates in immunocompromised patients have been found to be or may become resistant to ganciclovir.21 Ganciclovir also is effective against HSV, but isolates resistant to acyclovir also are resistant to ganciclovir.16,17 The most common therapy-limiting toxic effects of ganciclovir are granulocytopenia and thrombocytopenia, which usually are reversible when therapy ceases.

Cidofovir

Cidofovir (Vistide) is a nucleotide agent used to treat CMV retinitis in patients with human immunodeficiency virus (HIV) infection and for acyclovir-resistant HSV infections. It is available only for parenteral administration but has a long half-life, allowing a once-weekly dosing schedule of once per week or less frequent administration.22 The most common form of toxicity is renal insufficiency, which usually is reversible on discontinuation of the drug.

Foscarnet

Foscarnet (Foscavir, trisodium phosphonoformate hexahydrate, phosphonoformic acid) is an antiviral agent with activity against the human herpesviruses and HIV-1. It has been shown to be effective against CMV retinitis in AIDS patients and in acyclovir-resistant HSV and VZV infections.20,21 The main limiting form of toxicity with foscarnet is renal insufficiency, which usually is reversible after the drug is discontinued. Other side effects include malaise, headache, fatigue, nausea, vomiting, anemia, hypomagnesemia, hypophosphatemia, hyperphosphatemia, and hypocalcemia.

Vidarabine

Intravenous vidarabine (Vira-A, Adenine Arabinoside, Ara-A) can be effective for life-threatening HSV and VZV infections, but because of its potential for toxicity, acyclovir and foscarnet have largely replaced it.17

Trifluridine

Trifluridine 1% ophthalmic solution (Viroptic, Trifluorothymidine) is effective for treating primary keratoconjunctivitis and recurrent epithelial keratitis caused by HSV. Treatment of ocular infections should be undertaken in consultation with an ophthalmologist. Duration of treatment depends on the lesions’ response to the medication.

Interferon Alfa, Recombinant

Interferons are naturally occurring proteins with both antiviral and immunomodulating properties that are produced by host cells in response to an inducer. Injected intramuscularly, recombinant preparations of interferon-alfa (interferon alfa-2a [Roferon-A], interferon alfa-2b [Intron A], peginterferon-alfa-2b [PEG-Intron]) are effective in treating refractory condyloma acuminatum.23 High-dosage interferon therapy with subcutaneous injection of these agents has induced remission in cases of Kaposi’s sarcoma associated with HIV-1 infection.24 Patients with chronic hepatitis B who have lost hepatitis B e antigen with interferon therapy have better long-term outcome with
lower rates of end-stage liver disease and its complications.\(^{25}\) Newer agents for treatment of hepatitis B infection include lamivudine, adefovir, entecavir, and telbivudine.\(^ {26}\) Interferon alfa-2b combined with ribavirin has been shown to induce virologic and histologic response in patients with chronic hepatitis C infection.\(^ {27}\) Therapy is discontinued because of side effects in approximately 20% of patients. The side effects of interferon therapy include fever, malaise, headache, fatigue, alopecia, and bone marrow suppression. Use of newer pegylated interferons is now standard therapy for hepatitis C.\(^{28,29}\)

**Therapy for HIV Infection**

More than 30 antiretroviral drugs are currently available for the treatment of HIV infection (see Table 130–3). Treatment regimens usually include at least three of the recommended antiretroviral agents. Treatment of HIV infection is covered in Chapter 130.

**Therapy for Hepatitis B Infection**

At present, four antiviral agents are licensed for the treatment of chronic hepatitis B: lamivudine, adefovir, entecavir, and telbivudine. Additionally, emtricitabine, tenofovir, and their combined tablet, licensed for HIV infection, are off-label options. The treatment of hepatitis B infection is highly specialized. Treatment of hepatitis B infection is covered in Chapter 88.

### SPECIFIC VIRAL DISEASES

#### Infections Caused by DNA Viruses

**Poxviridae**

The elimination from the natural environment of variola virus, the virus that causes smallpox, at one time the most devastating worldwide pestilence, is one of the great medical and public health accomplishments of the past century.\(^ {6}\) The elimination of smallpox from the natural environment was possible because of the lack of nonhuman reservoirs or human carriers of variola and the availability of rapid diagnostic techniques and an effective vaccine. Global eradication was certified by the WHO in 1980. Other human poxvirus diseases include monkeypox, vaccinia virus infection, molluscum contagiosum, orf, and paravaccinia virus infection. The poxviruses are the largest pathogenic viruses, consisting of complex, brick-shaped capsids and double-stranded DNA.

**Variola (Smallpox), Monkeypox, Vaccinia, and Cowpox Viruses**

Within the Poxviridae family, the orthopoxvirus genus contains at least nine homogeneous viruses, including variola, vaccinia, cowpox, and monkeypox viruses. The last naturally acquired case of smallpox occurred in Somalia in October 1977.\(^ {9}\) Two cases occurred in 1978 in Birmingham, England, related to a research laboratory accident.

**Principles of Disease.** Recently, the possibility that military and research stores of virus could become weaponized and used as tools of terrorism or war has mandated that health care professionals familiarize themselves with the manifestations of smallpox, the clinical manifestations of vaccine-related illness, and the risks and benefits of the vaccine. The Centers for Disease Control and Prevention (CDC) has established extensive web-based information and training materials in preparation for the possibility of an outbreak.

**Clinical Features.** Smallpox is transmitted by infected droplets or close contact with a patient in any stage of illness. The most common manifestation in the unvaccinated host is variola major, which has a fatality rate of approximately 30%. The illness is characterized by a short prodrome of headache, backache, and fever. An ensuing enanthem progresses from small macules to papules and then vesicles over a few days. Lesions begin on the face and limbs and spread in a centrifugal pattern. These develop into 4- to 6-mm firm, deep-seated vesicles or pustules that umbilicate, crust, and then desquamate over the next several weeks (Fig. 128–1). All lesions are at the same stage of development. Modified, milder forms of smallpox can appear in previously vaccinated patients and, more rarely, in nonimmune hosts. There are also two more rare, but almost uniformly fatal, forms of smallpox: a fulminant, “hemorrhagic” form and “flat type” smallpox, characterized by plaquelike lesions.\(^ {30}\)

Major criteria for diagnosis include a prodrome of 1 to 4 days with fever (temperature higher than 38.3°C) with symptoms and signs such as headache and vomiting. Minor criteria include a centrifugal distribution of the rash, lesions on the palms and soles, a toxic appearance, and a rash that develops over several days. Routine laboratory tests are not helpful in the diagnosis. In the prodromal phase, there may be a relative granulocytopenia, but the white blood cell count usually is elevated in the eruptive phase. Laboratory diagnosis can be established by antibody testing, cell culture, or electron microscopy.

**Differential Considerations.** Smallpox has been confused with other papulovesicular eruptions, including varicella (chickenpox), measles, erythema multiforme, molluscum contagiosum, generalized vaccinia virus infection, and monkeypox. The lesions of chickenpox generally are at different stages of development and healing and often spare the palms and soles.

**Management and Disposition.** The CDC guidelines classify suspected cases of smallpox into categories of high, moderate, or low risk. Cases with high or moderate risk should prompt appropriate isolation and consultation with an infectious disease specialist or local health care authority. Quarantine, contact tracing, and immunization efforts are a priority for public health officials, and prompt involvement of the appropriate agencies will be crucial to containment efforts in the event of an outbreak.

Immunization with vaccinia virus was the cornerstone of smallpox containment and eradication efforts. Vaccinia virus immunization has been associated with morbidity and death in vaccinated persons and their close contacts. The decision to vaccinate must balance the risk of smallpox infection against the risk of vaccine-related injury. Pre-event vaccination is contraindicated in several groups of patients, including those who are pregnant, are breast-feeding, have significant immunosup-
pression, or have eczema. Close household contacts of persons at risk for serious side effects from vaccine should not be vaccinated. Recent mass vaccination campaigns have found a relatively low level of complications. There are no absolute contraindications to vaccination for persons who have been exposed to smallpox.

**Vaccinia Virus**

The origin of the vaccinia virus is not well established. Edward Jenner, in his “An Inquiry into the Causes and Effects of the Variolae Vaccinae” in 1798, observed that the putstrual material from the lesions of cowpox, when inoculated into humans, protected them from infection with smallpox.1

**Cowpox Virus**

Cowpox causes vesicular lesions on the udders and teats of cows. Human disease is manifested as vesicular lesions on the hands. Generalized infection is rare.

**Monkeypox Virus**

The disease of monkeypox is clinically similar to that of smallpox. Most cases have occurred in west and central Africa, with a case-fatality rate of 1 to 10% and higher death rates among children. An outbreak of 72 cases in the midwestern United States in spring 2003 was traced to contact with prairie dogs housed with Gambian giant rats that were imported from Ghana.32 No deaths were associated with this outbreak.

**Parapoxviruses, Molluscum Contagiosum, and Tanapox Viruses**

Other viruses within the Poxviridae family that cause disease in humans include the parapoxviruses (paravaccinia virus and bovine pustular stomatitis virus) and the molluscum contagiosum and tanapox viruses. The milker's node virus, or paravac-cinia virus, produces vesicular lesions on the udders or teats in cattle and is transmitted to humans by direct contact. Milker's nodules, which develop on the fingers or hands, are small, watery, painless nodules occasionally associated with lymphadenopathy. The lesions generally resolve completely within 3 to 8 weeks.

Bovine pustular stomatitis, erythema contagiosum, and orf viruses all cause papillomatous lesions on the mucous membranes and cornes of sheep. Single lesions generally develop in infected persons at the site of an abrasion.

Molluscum contagiosum is a generally benign human disease characterized by multiple small, painless, pearly, umbilicated nodules. They appear on epithelial surfaces, commonly in anogenital regions, and may be spread through close contact or autoinoculation. In immunocompetent persons, the lesions may clear rapidly or persist for up to 18 months. The infection often is seen in patients with HIV infection, in whom the lesions often are not restricted to the genital area and may increase in size and number.33 Curettage or other forms of local ablation may be helpful in such recalcitrant cases.

**Herpesviridae**

At least eight human herpesviruses are known. Herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) are the agents of herpes genitalis, labialis, and encephalitis. VZV is the agent of chickenpox and herpes zoster. Epstein-Barr virus (EBV) is the agent of infectious mononucleosis and also is associated with nasopharyngeal carcinoma, Burkitt’s lymphoma, and other lymphoproliferative syndromes. Cytomegalovirus (CMV) is associated with heterophile-negative infectious mononucleosis and invasive disease in immunocompromised patients. Human herpesvirus-6 (HHV-6) is associated with roseola infantum.34 The role of HHV-7 has not been completely elucidated. HHV-8 is associated with Kaposi’s sarcoma, body cavity–based lymphomas, and multicentric Castleman's disease. In addition, a closely related monkey virus, herpesvirus simiae or herpes B virus, has been shown to cause fatal encephalitis in humans.

**Herpes Simplex Virus**

**Principles of Disease.** A localized primary lesion, latency, and a tendency for local recurrence characterize infections with HSV-1 and HSV-2 (Herpesvirus hominis). The primary lesion with HSV-1 may be mild and inapparent; the first outbreak may occur during childhood. Reactivation of latent HSV-1 infection usually results in herpes labialis (cold sores, fever blisters). Neurologic involvement is not uncommon with HSV-1. Although such involvement usually occurs in association with a primary infection, neurologic signs may appear after a recrudescence and may manifest as encephalitis. Although uncommon, HSV-1 encephalitis is one of the most common causes of encephalitis in the United States, with estimates of several hundred to several thousand cases occurring yearly. HSV-2 most commonly is associated with genital herpes, although either HSV-1 or HSV-2 may infect any mucous membrane, depending on the route of inoculation. HSV-2 is commonly associated with aseptic meningitis rather than meningoencephalitis. The incubation period for primary herpes infection is 2 to 12 days.35

On contact with abraded skin or mucous membranes, HSV replicates locally in epithelial cells, which lyse and cause a local inflammatory response. Thin-walled vesicles on an erythematous base are the characteristic lesions of superficial HSV infection. Multinucleated giant cells with ballooning degeneration and intranuclear inclusions may be seen on a Tzanck preparation of a smear of material obtained from the base of these vesicles. After primary infection, HSV can become latent within sensory nerve ganglia. Emotional stress, sunlight, fever, or local trauma can trigger reactivation of the virus. HSV encephalitis usually involves the temporal lobes, resulting in a necrotizing, hemorrhagic encephalitis.

**Clinical Features.** Primary HSV-1 often is asymptomatic but may appear as pharyngitis and gingivostomatitis in children younger than 5 years. Associated with fever, pharyngeal edema, erythema, cervical adenopathy, and multiple small vesicles that ulcerate and multiply, the disease generally lasts 10 to 14 days. Recurrences occur in 60 to 90% of people after primary infection but generally are milder than the primary infection. Vesicles generally recur on the vermilion border, usually are small, and crust within 48 hours.

Herpes simplex infections of the eye most often are caused by HSV-1. Primary infections manifest as follicular conjunctivitis, blepharitis, or corneal epithelial opacities, which usually heal completely within 2 to 3 weeks. Recurrences may result in keratitis. Branching dendritic ulcers, detectable with fluorescein staining, are diagnostic and may result in diminished visual acuity. Deep stromal involvement may result in corneal scarring.

Primary herpetic finger infections (i.e., herpetic whitlow) generally are caused by HSV-1 among medical or dental personnel and by HSV-2 among the general population. The lesions are associated with intense pain and itching but generally resolve in 2 to 3 weeks. Recurrent whitlow with severe local neuralgia may occur.

Primary genital herpes generally is seen in the sexually active population and is caused by HSV-2 in 70 to 95% of cases. The lesions usually involve the shaft or glans of the penis in men and the vulva, perineum, buttocks, cervix, and vagina in women. Primary infection may be associated with...
fever, malaise, anorexia, and inguinal adenopathy. Vaginal discharge is common. Urinary involvement resulting in urinary retention is not uncommon in women. Herpetic sacral radiculomyelitis is uncommon but also can lead to urinary retention, myalgias, and obstipation. The lesions can last for several weeks before completely clearing. Recurrences of genital herpes generally are shorter and milder than the primary episodes and may be preceded by a prodrome of tenderness, itching, or tingling. Healing of recurrent lesions generally is complete in 6 to 10 days.

Primary perianal and anal herpes is common among persons who practice anal intercourse and may be especially prolonged and severe among HIV-1-infected patients.

Neonatal herpes infection occurs in 7 in 100,000 births and is caused by the transmission of the virus at the time of delivery. The rate of infection is estimated to be 40 to 50% after a primary maternal infection and less than 10% after a recurrence. The use of invasive monitoring and premature delivery also are associated with an increased risk of infection. Infection may manifest after several days to weeks with vesicles or conjunctivitis; neurologic involvement, with seizures, cranial nerve palsies, lethargy, and coma, is common. Untreated disseminated or CNS disease is fatal in more than 70% of patients.

Encephalitis caused by HSV is uncommon, but it is the most common acute, nonepidemic encephalitis in the United States. Cases do not have a seasonal distribution. Other than in the neonate, HSV-1 is the usual pathogen. The clinical disease begins acutely, with fever and focal neurologic signs, often localized to the temporal lobe. The patient may complain of a bad odor not perceived by anyone else (temporal lobe hallucination). Common clinical manifestations include headache, meningeal signs, lethargy, confusion, stupor, and coma. Cerebrospinal fluid (CSF) findings are nonspecific, with a moderate pleocytosis. Results of culture of the CSF generally are negative for HSV. Localization of the encephalitis within the temporal lobes by electroencephalogram, magnetic resonance imaging (MRI), or computed tomography (CT) scan increases the likelihood of a diagnosis of HSV encephalitis. The diagnosis of HSV encephalitis can be made reliably only with a biopsy of the lesion and subsequent isolation or detection of the virus by culture, direct fluorescent antibody tests, with a biopsy of the lesion and subsequent isolation or detection of the virus by culture, direct fluorescent antibody tests, or polymerase chain reaction (PCR) assay. The mortality rate among untreated patients approaches 80%, and less than 10% of patients are left with no neurologic sequelae. Treatment with acyclovir appears to reduce mortality and decrease the neurologic sequelae more effectively than treatment with vidarabine.

**Differential Considerations.** The superficial lesions of HSV infection are indistinguishable from those of VZV infection. Pharyngitis and gingivostomatitis in children can mimic streptococcal or diphtheritic pharyngitis, herpangina, aphthous stomatitis, Stevens-Johnson syndrome, Vincent’s angina, or infectious mononucleosis. Primary genital herpes can mimic the appearance of chancroid, syphilis, candidiasis, or Behçet’s syndrome. In the neonate, in the absence of vesicles, congenital HSV infection can mimic disease caused by rubella, cytomegalovirus, or *Toxoplasma* organisms. Encephalitis caused by HSV may be clinically indistinguishable from other viral encephalitides, tuberculous and fungal meningitis, brain abscesses, brain tumors, and cerebrovascular accidents.

**Management.** Oral acyclovir (400 mg three times daily), oral valacyclovir (1 g twice daily), or intravenous acyclovir (5 mg/kg three times daily) is recommended for treating primary genital herpes or mucocutaneous herpes in the immunocompromised host, although some authorities use higher dosages in these patients. Because of the safety and efficacy of oral acyclovir, there is little indication for using acyclovir ointment. In people with severe or frequent recurrences, acyclovir, ranging in doses from 200 mg five times daily to 800 mg once daily, can be used as an effective suppressive regimen. Both famciclovir and valacyclovir also are approved for suppressive therapy.

In the immunocompromised host, acyclovir is effective for both treatment and prophylaxis of recurrent mucocutaneous herpes. Foscarnet has been shown to be effective for the treatment of mucocutaneous herpes that is resistant to acyclovir.

**Disposition.** Patients with cutaneous HSV infections generally can be managed easily. The diagnosis often carries with it a great deal of stigma that must be addressed. Assurance of the generally benign nature of the infection is helpful. Counseling should include cautions about the transmissibility of the virus, even during asymptomatic periods. Women of childbearing age should discuss management of HSV infection during pregnancy and delivery with their obstetricians.

**Varicella-Zoster Virus**

Varicella-zoster virus (VZV), or human (alpha) herpesvirus-3, is the agent of both chickenpox and herpes zoster, or shingles.

**Clinical Features.** Chickenpox is an acute, generalized viral disease characterized by sudden onset of fever, malaise, and a skin eruption that initially is maculopapular and then becomes vesicular for several days before a granular scab is left (Fig. 128-2). Lesions occur in crops, with several stages present at the same time. Lesions can appear anywhere on the skin and mucous membranes. There may be few lesions and mild, inapparent infections. Most cases occur in children younger than 9 years; adults with the disease may have high fevers and severe constitutional symptoms. Children with acute leukemia are at increased risk for disseminated disease, which carries a case-fatality rate of greater than 5%. Neonates in whom varicella develops before 10 days of age and mothers who contract...
the disease in the perinatal period are at increased risk for generalized infection. Fatal disease in adults, although uncommon, is associated with pneumonic involvement. In children, fatal disease usually is associated with septic complications and encephalitis.

Herpes zoster is due to reactivation of VZV that has been latent in a dorsal root ganglion. Often preceded by tingling or hypesthesia, multiple vesicles on an erythematous base appear in crops along nerve pathways supplied by sensory nerves of a single or associated group of dorsal root ganglia. The distribution usually is unilateral and dermatomal (Fig. 128-3). Zoster occurs predominantly in older adults but has been seen in younger people when associated with HIV infection.42 The lesions often are extremely painful. Postherpetic neuralgia is common in the elderly, can last for months or years, and is refractory to treatment. Involvement of the ophthalmic branch of the trigeminal nerve may lead to corneal ulceration.

**Differential Considerations.** With chickenpox and herpes zoster, the diagnosis is clinical. Laboratory tests generally are not required. Multinucleated giant cells may be seen on Tzanck preparations of material from the base of a lesion, but these also can occur in herpes simplex lesions. Scrapings also can be submitted for antibody-linked fluorescent microscopy testing, which will yield rapid results and differentiate between HSV and VZV infection.

**Management.** Using acyclovir for uncomplicated chickenpox in children is safe but only modestly effective. Parents of children with chickenpox should be cautioned not to give their children aspirin or aspirin-containing compounds because of the strong association between this practice and the development of Reye’s syndrome.43 Acetaminophen can be used as an antipyretic. Adults experience increased morbidity and mortality from chickenpox, so treatment of otherwise healthy adults with acyclovir, famciclovir, or valacyclovir frequently is indicated. Patients with pneumonitis or other severe illness should be treated with intravenous acyclovir. In immunocompromised patients, varicella-zoster immunoglobulin and intravenous acyclovir have been shown to decrease morbidity.

A live, attenuated vaccine that shows a high degree of protection for both normal children and children with leukemia was licensed in the United States in 1995. It is recommended for immunocompetent people older than 12 months. In those older than 12 years, two doses of vaccine are to be administered 4 to 8 weeks apart. It also is recommended for use as PEP in the nonimmune host. The vaccine is most effective in preventing or attenuating illness in these circumstances if it is administered within the first 3 to 5 days after exposure.44 The vaccine is a live attenuated virus and not recommended for use in immunocompromised patients.

Uncomplicated herpes zoster generally is treated with supportive measures, especially pain control, and antivirals (acyclovir, famciclovir, or valacyclovir). Treatment with intravenous acyclovir should be considered for patients with disseminated disease and complicated zoster (involving more than one dermatome). Foscarnet is useful for treating infections due to acyclovir-resistant VZV in immunocompromised patients.16 Famiclovir may decrease the duration of postherpetic neuralgia. Susceptible immunocompromised patients exposed to infected persons should receive varicella-zoster immunoglobulin within 72 hours to prevent or modify clinical illness. Using corticosteroids to decrease the incidence of postherpetic neuralgia is controversial.

Herpes zoster is estimated to eventually occur in approximately 30% of the population, with the chance of an outbreak increasing with age. In persons older than 60 years, the possibility of developing postherpetic neuralgia is greater than 40%. Thus, it is currently recommended that immunocompetent persons older than 60 years be vaccinated with one dose of varicella zoster vaccine.11

**Disposition.** Chickenpox and herpes zoster are highly contagious. Although these diseases generally are benign, patients should avoid situations that put them in contact with steroid-treated or immunocompromised persons. The incubation period most commonly is 13 to 17 days, and the period of communicability may range from 5 days before to 5 days after the appearance of the vesicles. Susceptible persons should be considered potentially infectious from 10 to 21 days after exposure. Susceptible health care workers should not care for people with varicella or zoster. Health care workers without a well-documented history of chickenpox or herpes zoster should have antibody levels checked before they begin their employment to determine susceptibility to VZV, and they should strongly consider vaccination if they prove to be nonimmune.

**Cytomegalovirus**

**Principles of Disease.** CMV, or human herpesvirus-5, commonly is associated with heterophile-negative infectious mononucleosis syndrome and is clinically and hematologically similar to EBV-associated mononucleosis. More severe infections with CMV occur in the perinatal period and among immunocompromised patients. Severe CMV infections also are found in transplant recipients when organs from CMV-seropositive donors are transplanted into CMV-seronegative recipients.

Primary infection with CMV often is associated with a vigorous T lymphocyte response. CMV persists indefinitely, probably within multiple cell types in various organs. Reactivation leading to CMV-associated disease may occur in response to a variety of external stimuli.

**Clinical Features.** CMV infection in immunocompetent older children and adults generally is subclinical. It is characterized by fever, lymphadenopathy, exudative pharyngitis, and peripher al lymphocytosis, with atypical lymphocytes present on peripheral blood smears. The acute infection resolves in 2 to 4 weeks, but malaise and viral excretion can persist for months. In the perinatal period, severe, generalized infection can occur and may be associated with lethargy, convulsions, jaundice, petechiae, hepatosplenomegaly, chorioretinitis, and pulmonary infiltrates. Survivors may exhibit various degrees of neurologic impairment. Fetal infection can occur after primary or reactivated maternal infections, with primary infections carrying a much higher risk. Severe, generalized disease can occur in immunocompromised patients and often is associated with severe end-organ disease, such as colitis, esophagitis, pneumonitis, retinitis, and adrenalitis. Retinitis caused by CMV was the most common cause of blindness among people with AIDS in the pre-HAART era, but its incidence has fallen precipi-
tously. CMV can cause a polyradiculopathy and other, less common neurologic manifestations in patients with AIDS or other conditions of immunocompromise. Therapy with ganciclovir and foscarnet is indicated, but treatment results may be disappointing.45

**Differential Considerations.** Mononucleosis caused by CMV may be clinically indistinguishable from syndromes caused by EBV or *Toxoplasma*. In the perinatal period, infants with generalized infections require evaluation for other common perinatal infections, such as toxoplasmosis, rubella, syphilis, and HSV infection. Recipients of organ transplants and other immunocompromised patients with fever and other signs and symptoms of generalized infection require intensive evaluation for bacterial and viral causes of infection. Diagnosis of CMV infection depends on viral isolation, detection of CMV pp65 antigen, or the demonstration of a fourfold rise in antibody to viral antigens.

**Management.** Only supportive care is indicated for infected immunocompetent adults and children, and they generally can be managed at home. CMV infection in the perinatal period or complicated by impairment of immune function can be life-threatening, and patients in whom such infections are suspected generally require hospitalization for aggressive evaluation, monitoring, and specialized care. Valganciclovir, ganciclovir, foscarnet, and cidofovir are all useful in treating CMV infections in immunocompromised patients.

**Epstein-Barr Virus (Infectious Mononucleosis)**

**Principles of Disease.** EBV, or human herpesvirus-4, most commonly is associated with infectious mononucleosis, an acute viral syndrome characterized by fever, exudative pharyngotonsillitis, lymphadenopathy, and peripheral lymphocytosis with atypical lymphocytes. EBV also has been strongly implicated in the pathogenesis of African Burkitt’s lymphoma and nasopharyngeal carcinoma. Acute immunoblastic sarcoma, involving a polyclonal expansion of EBV-infected B lymphocytes, may occur in people with an X-linked immunoproliferative syndrome. Hodgkin’s disease and other lymphomas in immunocompromised patients, such as renal transplant recipients or persons with AIDS, also have been associated with EBV infection. A chronic form of the disease has been suggested as the cause of chronic fatigue syndrome, but data supporting this association are limited.46

EBV infects and transforms B lymphocytes. Infection is common and widespread in early childhood in developing countries, where it usually is mild or asymptomatic. In developed countries, infectious mononucleosis usually manifests in older children and young adults, commonly among high school and college students. It is transmitted by way of the oropharyngeal route, often by kissing. The incubation period may be as long as 4 to 6 weeks, and pharyngeal excretion can persist for 1 year or more.

**Clinical Features.** The syndrome usually is mild in children, but 95% of young adults have abnormal transaminases and 4% have jaundice. Hepatosplenomegaly is common. Severe exudative pharyngitis, fevers, lymphadenopathy, and fatigue are characteristic of infectious mononucleosis. The disease generally resolves in 1 to 3 weeks, but malaise and fatigue rarely can persist for several months. Occasionally, tonsillar swelling causes respiratory compromise. Splenic rupture is rare but must be considered in patients with left upper quadrant pain and a falling hematocrit. Neurologic complications, including encephalitis, aseptic meningitis, transverse myelitis, Guillain-Barré syndrome, optic neuritis, and peripheral neuropathies, occur in less than 1% of patients.

**Diagnostic Strategies and Differential Considerations.** Laboratory diagnosis is based on the finding of lymphocytosis (greater than 50% of the total white cell count) or an elevation in heterophile antibodies (Monospot test). Heterophile antibodies are sensitive and specific antibodies that usually appear early in the illness. Other assays for virus-specific antibodies are available but rarely are needed to diagnose mononucleosis, because in 90% of cases the patient is heterophile-seropositive.

A presumptive diagnosis can be made on the basis of the finding of significant cervical lymphadenopathy, particularly posterior cervical, and exudative pharyngitis coupled with a lymphocytosis and the presence of atypical lymphocytes on a blood smear. HHV-6, cytomegalovirus, and toxoplasmosis can cause syndromes that are clinically and hematologically similar to infectious mononucleosis.

**Management.** Treatment is supportive only, except when rare complications of organ compromise are present. The use of corticosteroids in uncomplicated illness is controversial. These agents generally are used for impending airway obstruction, hemolytic anemia, or severe thrombocytopenia. Infection confers a high degree of resistance to reinfection. Patients should be cautioned about potential communicability to previously uninfected people.

**Human Herpesvirus-6**

**Principles of Disease.** HHV-6 has been implicated as an agent of roseola infantum (exanthem subitum).34

**Clinical Features.** Roseola infantum is the most common exanthem of children younger than 2 years of age and occurs most often at approximately 1 year of age. The illness begins abruptly with the acute onset of fever, often as high as 41°C, lasting 3 to 5 days. A fine, evanescent, rose-colored maculopapular rash appears on the trunk after lysis of the fever and lasts for 1 to 2 days. The rash may spread to the face and extremities. Most cases are self-limited, and despite the fever, the child usually remains active and alert. HHV-6–associated febrile seizures are thought to account for a significant percentage of ED visits for pediatric fever and febrile seizures.37 Although secondary cases occur after an incubation period of approximately 10 days, most cases of roseola occur without known exposure.

**Differential Considerations.** The disease appears similar to other childhood exanthems. The child generally looks well despite the high fever.

**Management.** Acetaminophen may reduce the fever. Routine supportive measures should be used if febrile seizures occur.

**Human Herpesvirus-7**

HHV-7 has been associated with a clinical presentation similar to that for HHV-6, but its role in disease has not yet been fully elucidated.38

**Human Herpesvirus-8 (Kaposi’s Sarcoma–Associated Herpesvirus)**

HHV-8 has been implicated as the cause of Kaposi’s sarcoma regardless of the HIV serostatus of the affected patient.59

Mechanisms of disease pathogenesis as well as epidemiology of transmission for this virus remain unclear and continue to be actively investigated.

**Herpes B Virus**

**Principles of Disease.** Herpes B virus, or herpesvirus simiae, is closely related to human herpes simplex virus, is enzootic in macaques and most commonly is associated with Rhesus, cynomolgus, or African green monkeys. Like human herpes simplex virus, herpes B virus produces mild disease in monkeys that is characterized by intermittent reactivation and shedding, particularly during times of stress, such as during handling. Among monkey handlers and those exposed to the animals’ saliva or tissues, monkey B virus is a serious occupational hazard. Of 23 symptomatic human infections, 18 resulted in a progressive
muco-cutaneous disease and fatal encephalitis. The first known case of fatal herpesvirus B infection, from a mucosal splash exposure, occurred in 1998.

**Postexposure Management.** The most important step that can be taken to prevent B virus disease is thorough cleansing of exposed tissues. Current recommendations are that mucous membranes be flushed with sterile saline or water for 15 minutes and that areas of exposed skin be washed for 15 minutes with a detergent or a solution containing disinfectants (such as chlorhexidine or povidone-iodine). Affected tissue (except ocular or mucous membranes) can be initially washed with 0.25% hypochlorite (Dakin’s) solution before being washed with a detergent solution.

The decision to initiate PEP is based on the severity of the exposure and the appropriateness of first aid measures. PEP does not need to be initiated if the exposed skin is intact or the exposure is to a nonmacaque species of monkey. Valacyclovir does not need to be initiated if the exposed skin is intact or exposure is to a nonmacaque species of monkey. Valacyclovir, 1 g PO every 8 hours for 14 days, is recommended for PEP.

**Clinical Features.** After a penetrating bite or scratch from an infected monkey, herpetiform vesicles may form at the site of the injury. Giant cells can be seen on a Tzanck preparation. An acute febrile illness with headache and lymphocytosis may follow as late as 3 weeks after the injury. An ascending myelitis ensues, leading to death from respiratory paralysis or encephalomyelitis within 3 weeks of onset of symptoms. The incidence of asymptomatic infection is unknown.

**Differential Considerations.** The initial skin lesions appear similar to those of herpes simplex. In the context of any exposure to monkey tissues and the appearance of a herpetiform lesion, the diagnosis of herpes B virus infection must be considered because of its associated high mortality rate.

**Treatment.** Suspected B virus infection constitutes a medical emergency. Aneurysmal reports have described successful prevention of disease progression with intravenous acyclovir. The apparent response of the infection to appropriate regimens emphasizes the need for early recognition and treatment. If CNS symptoms are present, ganciclovir is the drug of choice.

**Adenoviridae**

**Adenovirus**

**Principles of Disease.** Adenoviruses are the most clinically important viruses because of their capacity to cause upper respiratory tract infections, conjunctivitis, and gastroenteritis. Nevertheless, no drugs or therapeutic measures specifically effective for adenoviral infections are available.

**Clinical Features.** Adenoviruses cause respiratory diseases ranging from pharyngitis and tracheitis to fulminant broncholitis and pneumonia. Cough, fever, sore throat, and rhinorrhea are the most common symptoms and generally last only a few days. Pneumonitis with interstitial infiltrates are occasionally seen with some strains. Upper respiratory findings may be associated with conjunctivitis (pharyngoconjunctival fever). Adenoviruses may cause an epidemic keratoconjunctivitis, which in severe cases may be associated with conjunctival scarring. Other syndromes associated with adenoviruses include hemorrhagic cystitis, infantile diarrhea, intussusception, encephalitis, and meningoencephalitis.

**Differential Considerations.** Other pathogens causing similar atypical pneumonia syndromes include influenza and parainfluenza viruses and *Mycoplasma pneumoniae*. Diarrheal syndromes may be similar to those caused by rotaviruses.

**Management.** Treatment for adenovirus infections is supportive.

**Papillomaviridae**

**Principles of Disease.** HPVs cause a variety of cutaneous and mucous membrane lesions, including common warts, anogenital or venereal warts (condyloma acuminatum), and respiratory or laryngeal papillomas.

More than 70 types of HPVs have been identified. Laryngeal papillomas (most commonly caused by HPV types 6 and 11) and genital warts (most commonly caused by HPV types 16 and 18) can undergo malignant transformation.

The association between HIV infection and more aggressive forms of HPV infection, including a greater likelihood for malignant transformation of lesions, has been shown.

**Clinical Features.** Common warts generally are well-circumscribed, hyperkeratotic, painless papules occurring most commonly on the extremities and transmitted by close personal contact. Plantar warts, found on the soles of the feet, may be very painful. Venereal warts, found on the internal or external genitalia or perianal region, are hyperkeratotic, exophytic papules, either sessile or pedunculated, and are sexually transmitted. Laryngeal papillomas in children presumably are acquired during passage through the birth canal. Malignant transformation can occur, particularly in patients receiving radiation therapy.

**Differential Considerations.** The diagnosis of warts usually is made clinically. Condyloma acuminatum must be distinguished from the condyloma latum of syphilis. Diagnosis of cervical HPV infections can be made during colposcopy with previous application of a 3 to 5% acetic acid solution to the internal genital tract. Flat condylomata appear as shiny white patches with ill-defined borders and irregular surfaces. Acetowhitrning also can reveal subclinical vulvar or penile warts.

**Management.** Genital warts generally regress spontaneously within months or years, and it is unclear whether their removal decreases infectivity or decreases the chance of malignant transformation. Therapy is at the discretion of the patient and the caregiver. Patient-applied therapies use podophlox 0.5% gel or imiquimod 5% cream. Freezing with liquid nitrogen, surgical removal, and intralesional interferons also are effective for most accessible lesions. Combination therapies also can be used. Salicylic acid plasters and curettage are useful for plantar warts. Laryngeal warts require surgery or laser therapy.

**Polyomaviridae**

**Principles of Disease.** JC virus and BK virus are human polyomaviruses that cause ubiquitous but asymptomatic infection in populations worldwide. Progressive multifocal leukoencephalopathy (PML) is a rare, slowly progressive, demyelinating CNS disease associated with JC virus. The demyelinated lesions of PML slowly enlarge to become large plaques, associated with progressive neurologic deterioration, dementia, and eventually death. The disease occurs mostly in severely immunocompromised patients. Similarly, BK virus viruria is relatively common in immunosuppressed patients or pregnant women. Rare, symptomatic infection can manifest as urethral stenosis in renal transplant recipients and as hemorrhagic cystitis in bone marrow transplant recipients.

**Clinical Features.** Initial presentations of PML in immunocompromised patients include paresis, personality changes, and impaired higher cortical functioning. The disease generally is rapidly progressive, usually progressing to death within 2 to 4 months of the initial neurologic symptoms. PML commonly is seen in people with advanced AIDS.

**Differential Considerations.** Considerations in the differential diagnosis include other causes of progressive neurologic
disease in immunocompromised patients—toxoplasmosic encephalitis, primary CNS lymphoma, HIV encephalopathy, tuberculous meningitis, vascular disease, and others. A lack of enhancement on contrast CT and MRI scans is helpful in making the diagnosis. PCR assay identification of JC virus in the appropriate clinical setting with consistent radiographic findings establishes the diagnosis.56

**Management.** No specific treatment for PML is available; the disease generally is rapidly progressive, and ultimate transfer to appropriate nursing care facilities often is necessary. Recently, there have been reports of significant improvements to appropriate nursing care facilities often is necessary.

**Infections Caused by RNA Viruses**

### Reoviridae

The family Reoviridae (respiratory enteric orphan viruses) includes four viruses causing human disease: orthoreovirus, orbivirus, coltivirus, and rotavirus. The reoviruses commonly infect humans but infrequently cause human disease. Upper respiratory infections, exanthems, pneumonia, hepatitis, encephalitis, gastroenteritis, and biliary atresia have on occasion been associated with these viruses.

### Colorado Tick Fever

**Principles of Disease.** Colorado tick fever, or mountain fever, is caused by a coltivirus similar to the orbiviruses that are transmitted to humans through the bite of the hard-shelled wood tick *Dermacentor andersoni*. It occurs primarily in the western United States, but a serotype has been isolated from the *Ixodes ricinus* tick in Germany and from the dog tick, *Dermacentor variabilis*, in Long Island, New York. Illness generally occurs in late spring through summer (see also Chapter 132). **Clinical Findings and Features.** The incubation period for Colorado tick fever is 3 to 6 days, and a history of tick exposure is elicited in 90% of patients. The disease generally occurs in people engaged in activities that bring them into contact with ticks. The fever is biphasic, as indicated by a “saddle-back” curve plotting temperatures over time, with the patient initially acutely experiencing chills, lethargy, prostration, headache, ocular pain, photophobia, abdominal pain, and severe myalgias. The initial fever lasts 2 to 3 days, recedes for a similar period, and then is followed by a second fever lasting approximately 3 days. Rash, occasionally petechial, is uncommon, occurring in 5 to 10% of patients. Meningoencephalitis is a rare but serious complication in children. Convalescence lasts 1 to 3 weeks; one half of infected persons are viremic 4 weeks after the onset of illness.61

**Differential Considerations.** Colorado tick fever commonly is misdiagnosed as Rocky Mountain spotted fever. Patients with fever and rash after tick bites in endemic areas should be treated for Rocky Mountain spotted fever. Confirmation of the diagnosis of Colorado tick fever is by mouse inoculation or fluorescent staining of erythrocytes.

**Management.** Treatment is supportive and symptomatic.
Six orbiviruses have been implicated in human disease. Chan-quinola virus is transmitted from Phlebotomus flies; Lebombo and Orungo viruses from mosquitoes; and Kemerovo, Lipovnik, and Tribec viruses from ticks. All six have been associated with febrile illnesses and, rarely, encephalitis.

Rotavirus

**Principles of Disease.** Rotaviruses derive their name from their wheel-like appearance on transmission electron microscopy. These organisms cause severe gastroenteritis in infants and young children, particularly between the ages of 6 months and 2 years; the gastroenteritis is manifested by severe diarrhea and vomiting, which often lead to dehydration and occasionally death. In temperate climates, illness occurs mainly in the winter, commonly is associated with nosocomial infection, and is spread primarily from person to person by the fecal-oral route. The incubation period is approximately 2 days.

**Clinical Features.** Mucosal epithelial cells of the small intestine appear to be infected selectively, leading to shortening of villi and decreased absorption of salt and water. A secretory diarrhea is produced with impaired d-xylene absorption. Clinical disease ranges from asymptomatic to severe, fatal diarrhea and dehydration. The illness is abrupt in onset with nausea, vomiting, watery diarrhea, low-grade fever, headache, and myalgias. The course of the disease generally is 3 to 5 days in duration. Fatalities are common in developing countries but rare in developed regions of the world. In newborns, rotavirus has been associated with neonatal necrotizing enterocolitis. Infections in adults usually are asymptomatic.

**Differential Considerations.** Rotavirus enteritis should be suspected in any child with watery diarrhea occurring during the cooler months of the year. Fecal leukocytes and erythrocytes generally are not seen in rotaviral diarrhea. Other enteric viruses can produce a clinical syndrome similar to that due to rotavirus. Radioimmunoassays, enzyme immunoassays, and latex agglutination methods for detecting antigen are highly reliable and available at most hospital laboratories.

**Vaccination.** An attenuated human rotavirus vaccine and a human-bovine reassortant rotavirus vaccine have been shown to be both efficacious and safe in trials conducted in both developed and developing countries. Currently, the human bovine reassortant vaccine is approved in the United States as a three-dose (at 2, 4, and 6 months of age) orally administered live vaccine.

**Management.** Specific treatment for rotaviral infections is not currently available. Intravenous fluids provide effective therapy for dehydration, but if the patient tolerates oral fluids, oral rehydration using packaged oral rehydration salts can be used in the outpatient setting for mild to moderate dehydration.

Togaviridae

**Alphavirus (Group A Arbovirus)**

**Principles of Disease.** Arboviruses (arthropod-borne viruses) are transmitted to humans by an arthropod vector; humans usually are an unimportant host in the reproductive cycle of the virus. Most arboviruses are mosquito-borne, but ticks, sandflies, gnats, and midges serve as important vectors for some diseases. The alphaviruses and flaviviruses are the most common arboviruses causing disease in humans, but some bunyaviruses, reoviruses, rhabdoviruses, filoviruses, arenaviruses, and orthomyxoviruses also are transmitted by arboviral vectors.

The alphaviruses are transmitted by the bite of a mosquito. The three alphaviruses that cause human disease in the United States are the agents of eastern equine encephalitis, western equine encephalitis, and Venezuelan equine encephalitis. Other important alphaviruses include the Chikungunya (Africa, Southeast Asia, Philippines), Mayaro (South America), O’nyongnyong (Africa), Ross River (Australia, South Pacific), and Sindbis (Africa, Asia, Soviet Union, Australia, and Scandia-navia) viruses.

**Clinical Features.** These arboviruses can cause outbreaks of encephalitis in various parts of the United States. The few annual cases of eastern equine encephalitis in the United States occur predominantly near freshwater swamps of the Eastern seaboard. Although more than 95% of cases are subclinical, the mortality rate among patients presenting with clinical encephalitis approaches 50%. Infections occur most commonly in children younger than 10 years of age or in the elderly. The onset of symptoms often is fulminant, with headache, fever, and convulsions progressing rapidly to decreasing level of consciousness and death. Focal neurologic deficits also may develop. Western equine encephalitis is present throughout the United States but occurs mostly in the western and central parts of the nation. Children younger than 1 year and elderly persons are most often affected. More than 99% of cases are inapparent, and the encephalitis usually is mild, with an associated mortality rate of approximately 3%. Venezuelan equine encephalitis is found predominantly in Central and South America, but the disease has been seen in Texas and Florida. Venezuelan equine encephalitis usually manifests as an influenza-like illness. One third of patients have encephalitis, with a mortality rate of less than 1%, predominantly in children.

**Differential Considerations.** Other viral causes of encephalitis in the United States include HSV, HIV, St. Louis encephalitis (a flavivirus), California (La Crosse) encephalitis (a bunyavirus), and the recently encountered West Nile–like encephalitis (a flavivirus). Other viruses, such as mumps, rabies, polio, and other enteroviruses, can also manifest as encephalitides. The WBC count in the CSF of persons with eastern equine encephalitis may be very high, and the diagnosis of meningoencephalitis must be considered. Diagnoses can be confirmed by a rise in antibody titers.

**Management.** Management is supportive only. For people with expected intensive exposure to these viruses, an investigational vaccine may be available from the U.S. Army Medical Research Institute for Infectious Diseases in Fort Detrick, Maryland.

**Rubella Virus (German Measles)**

**Clinical Features.** Rubella is a mild febrile illness associated with a diffuse maculopapular rash, fever, malaise, headache, and postauricular, occipital, and posterior cervical lymphadenopathy (Fig. 128-5).

Transmission of rubella is through contact with respiratory secretions. The incubation period of rubella ranges from 12 to 23 days. Accompanied by viremia, the rash usually lasts 3 to 5 days. The disease is highly communicable from approximately 1 week before to 4 days after the onset of the rash. The most common complications of rubella are arthropathies, or frank arthritis, predominantly affecting the fingers, wrists, and knees; the arthropathies may persist for several months. Encephalitis and thrombocytopenia are rare complications.

Although the disease generally is a mild, febrile illness in children and adults, the consequences of rubella occurring during pregnancy (congenital rubella syndrome) may be tragic. Severe consequences include fetal death, premature delivery, and a variety of congenital defects, including hearing loss,
cataracts, retinopathy, mental retardation, and a variety of cardiac abnormalities. The younger the fetus is at the time of a maternal infection, the more likely it is that the fetus will be affected. During the first 2 months of pregnancy, the fetus has an approximately 90% chance of being affected. The risk decreases to approximately 80% during the third month and to 66% during the fourth month. No congenital defects were found in 106 children born to mothers after laboratory-proven maternal infection contracted after the 17th week of pregnancy.69

**Differential Considerations.** The rash associated with rubella (“third disease”) is one of the classic common exanthems of childhood. It may be similar to the rash of measles (rubeola, or “first disease”), scarlet fever (“second disease”), a variant of scarlet fever or toxin-producing staphylococcal disease (“fourth disease”), erythema infectiousum (“fifth disease”), and roseola (exanthem subitum, or “sixth disease”).70

**Management.** Rubella control is required to prevent birth defects in the offspring of women who develop the disease during pregnancy. In the United States, vaccination to prevent rubella is recommended for all children at the age of 15 months. Vaccination results in a greater than 95% seroconversion rate. Because of the production of a transient viremia, pregnancy should be delayed for 3 months after a susceptible woman has been vaccinated. No cases of the congenital rubella syndrome attributable to rubella vaccine occurred in more than 300 women inadvertently vaccinated during pregnancy who carried their infants to term.71 There is no evidence of decreasing immunity with age. Persons with rubella should be cautioned to avoid contact with susceptible women. Because of an increasing failure to vaccinate susceptible persons, a moderate resurgence of rubella and a major increase in the congenital rubella syndrome in the United States occurred in 1990.72 Since then, a general decline in rubella incidence has been observed, but outbreaks continue to occur, especially among foreign-born adults.73

**Flaviviridae**

**Flavivirus (Group B Arbovirus)**

More than 60 flaviviruses have been identified, with more than 20 causing human disease. Four of the most common, all transmitted to humans by a mosquito vector, are the agents of yellow fever, dengue, St. Louis encephalitis, and West Nile virus.

**Clinical Features.** Yellow fever is present in tropical South America and Africa. Fever, chills, headache, nausea, and vomiting follow a 3- to 6-day incubation period.74 The disease may be biphasic, with fever, jaundice, hemorrhage, and characteristic “black vomit” (from the coagulopathy secondary to an affected liver) occurring after a brief period of remission. The case-fatality rate is 5%.

Dengue occurs in tropical areas worldwide. Classic dengue fever (breakbone fever) is a nonfatal disease characterized by fever, headache, arthralgias, weakness, nausea, and anorexia after an incubation period of 5 to 10 days. Patients may experience severe bone pain. A generalized macular rash that occasionally desquamates may be seen. The fever lasts 5 to 7 days, but the recovery period may be prolonged. Dengue hemorrhagic fever, characterized by increased vascular permeability and bleeding associated with thrombocytopenia, carries a mortality rate of less than 5% in people who receive good medical care but up to 50% in those left untreated. The number of reports of dengue transmission within the United States on the U.S.-Mexico border in Texas and in Hawaii has been increasing.75,76 With a population that shows evidence of previous exposure to dengue fever and the continued presence of the *Aedes aegypti* mosquito, the potential for cases of dengue hemorrhagic fever in persons without a recent history of foreign travel certainly exists. The possibility of dengue fever and its hemorrhagic form should be considered in all persons presenting with suggestive symptoms, even if they have not traveled outside the United States.

**St. Louis encephalitis** occurs in the summer in most areas of the Western Hemisphere. After an incubation period of 4 to 21 days, infection with the *St. Louis encephalitis* virus can produce fever and headache, aseptic meningitis, or encephalitis. The mortality rate associated with the encephalitis approaches 10%. The disease commonly affects the elderly.

**West Nile virus** causes a febrile illness, with potential for meningoencephalitis. It was first described in the United States in 1999 but also has caused illness in many areas of Africa, Asia, and Europe.77 In 2003, the CDC confirmed 9858 cases and 262 deaths attributable to West Nile virus, qualifying this epidemic as the largest outbreak of arboviral meningoencephalitis recorded in the Western hemisphere.78 The primary cycle of infection is maintained by vector mosquitoes in bird populations. Humans are infected by cross-feeding mosquitoes. The virus has disproportionately affected certain bird populations in the United States, resulting in bird deaths. Recognition of this phenomenon led to early elucidation of the life cycle and has helped in characterization of the zoonotic activity of the virus.68

Non–arthropod-borne human cases from laboratory transmission and person-to-person transmission by blood transfusion, organ transplantation, maternal-fetal transmission, or breast-feeding have been documented. These modes of transmission account for a small number of cases.77 It is now very clear that the virus has established itself in North America, and yearly outbreaks are to be expected. The peak incidence of disease is during the months of July through October; however, as the disease has moved into the southern states, transmission is being reported as early as April and as late as December.77
The incubation period for West Nile virus appears to be 3 to 14 days. West Nile fever will develop in 20% of infected persons, and meningitis or encephalitis will develop in 1 in 150. West Nile fever usually is characterized by fever, headache, myalgia, anorexia, and lymphadenopathy; half of infected patients develop a maculopapular central rash. West Nile virus meningoencephalitis is characterized by fever, headache, mental status changes, and motor disturbances that range from generalized weakness to myoclonus, tremor, and parkinsonian movement disorders. A poliomyelitis-like syndrome has been described. Cranial nerve and bulbar abnormalities can be seen.

Laboratory testing is nonspecific. CSF findings in patients with meningoencephalitis are similar to those with other viral infections: elevated protein level, normal glucose level, and a mild to moderate pleocytosis with a lymphocytic predominance. Viremia usually clears by the onset of meningoencephalitis, but IgM can be detected in the CSF. IgM levels in the serum can remain elevated long after clinical illness has resolved. Imaging studies are nondiagnostic, but the MRI scan can show nonspecific leptomeningeal inflammation.

Disease outcome is related to patient age; elderly persons are at significantly higher risk for the development of encephalitis and death from West Nile virus infection. Patients with disease severe enough to necessitate hospitalization often have long-term sequelae.

**Differential Considerations.** The differential diagnosis for yellow fever is broad in scope; considerations include hepatitis, malaria, typhoid, dengue, and other viral hemorrhagic fevers in endemic areas. Viral antigen detected in the blood by enzyme-linked immunoadsorbent assay provides for a rapid diagnosis. The differential diagnosis for dengue is similar to that for yellow fever. Diagnosis is made by viral isolation or serology. St. Louis encephalitis can manifest like other causes of meningoencephalitis. In the elderly, it may be misdiagnosed as stroke. Diagnosis is made by serology. West Nile virus infection occurs most often in the summer and fall and may be clinically indistinguishable from other arboviral illnesses. CSF IgM antibody testing is the best means of establishing the diagnosis, but results may be falsely positive after other flaviviral infections such as St. Louis encephalitis, or after immunization against yellow fever.

**Management.** Treatment for these viral diseases is supportive. The diseases are not contagious through person-to-person contact, but the virus generally is transmissible to the mosquito vector during the period of clinical illness. Control of epidemics is achieved by reducing the mosquito vector populations and limiting access of mosquitoes to infected hosts. Persons traveling to endemic areas should be vaccinated for yellow fever.

No recommended therapies are currently available for West Nile virus infection. Treatment is supportive. Suspected disease should be reported to public health authorities. Control of West Nile virus infection will rest in control of vector mosquito populations. Physicians should join public health officials in aggressive efforts to educate the public on mosquito control and bite protection measures, such as the use of repellents and protective clothing.

**Hepatitis C**

Hepatitis C, now classified in its own genus, Hepacivirus, within the Flaviviridae, is an important contributor to morbidity and mortality throughout the world. In the United States, hepatitis C formerly was associated with most cases of posttransfusion (non-A, non-B) disease. As a result of testing the blood supply, the incidence of transfusion-related hepatitis C has decreased. However, the prevalence of infection remains high in certain populations, such as injection drug users. In the United States, it is estimated that 3.9 million people have hepatitis C infection.

Chronic hepatitis C infection has been associated with cirrhosis and hepatocellular carcinoma. Estimates of the rate of long-term morbidity and mortality resulting from chronic hepatitis C vary. The likelihood of developing cirrhosis ranges from 5 to 25% in different studies. Hepatitis C is discussed further in Chapter 88.

**Coronaviridae**

**Coronavirus**

**Principles of Disease.** The severe acute respiratory syndrome (SARS) was first documented in China’s Guangdong province in November 2002. By the time the epidemic was contained in July 2003, it had affected approximately 8000 persons in 29 countries, with a case-fatality rate of approximately 10%. The causative agent was identified as a novel coronavirus (SARS-CoV). Early in the epidemic, astute researchers noted that the illness was more prevalent among restaurant workers and focused attention on live animals that were being sold for human consumption. Their efforts revealed that the virus was transmitted to humans by handling and consumption of wild mammals, such as the civet.

By 2003, 161 cases of SARS had been reported in the United States. Of these, 8 were confirmed and 153 are still under investigation, but no U.S. deaths were reported that were attributable to SARS. Most patients had traveled to an area of documented or suspected SARS transmission.

The SARS epidemic has posed a challenge to national and international agency-based medical personnel and public health authorities. Public health measures have been implemented to contain the infection and establish sentinel systems to warn of recurrent outbreaks. Health care practitioners, especially ED personnel, should notify local public health authorities of suspected or confirmed cases of SARS.

**Clinical Features.** The current CDC case definition for SARS-CoV disease includes the presence of laboratory-confirmed infection or severe respiratory illness in the setting of epidemiologic criteria for likely exposure to SARS-CoV. Early disease is defined by the presence of two or more of the following features: fever (which may be subjective), chills, rigors, myalgia, headache, diarrhea, sore throat, and rhinorrhea. Mild to moderate disease requires presence of fever with temperature greater than 38°C and evidence of lower respiratory tract illness. Severe respiratory illness is defined as noted previously but also includes radiographic evidence of pneumonia or acute respiratory distress syndrome. Laboratory diagnosis of the disease relies on SARS-CoV antibody testing, cell culture, or reverse transcription–PCR techniques. Epidemiologic criteria for possible exposure include travel within the past 10 days to an area with documented or suspected recent transmission of SARS-CoV or close contact with a symptomatic person who recently engaged in such travel. Epidemiologic criteria for likely exposure requires that transmission be somehow linked to a person with confirmed disease.

Retrospective analyses of the SARS-CoV infection outbreak suggest an incubation period of 3 to 10 days with an ensuing viral prodrome characterized by headache, malaise, and myalgias. Fever, clinical evidence of upper and lower respiratory infection, dyspnea, and gastrointestinal disturbances also may be features. Chest radiographs are normal in appearance in up to 25% of patients with early infection, despite the presence of fever and respiratory complaints. CT scans may be more useful in identifying early pulmonary involvement. Hypoxemia, with clinical and radiographic evidence of pneumonia,
develops as the disease progresses. In a minority of patients, progressive respiratory failure and acute respiratory distress syndrome may follow. Patients older than 60 years and those with comorbid illness such as diabetes mellitus have worse outcomes.89,93

Laboratory findings are nonspecific but include lymphopenia, thrombocytopenia, elevated lactate dehydrogenase, and prolonged activated partial thromboplastin time. Hemolytic anemia and electrolyte disturbances, such as severe hypomagnesemia with associated tetany, have been reported.92

Differential Considerations. The clinical features of SARS-CoV mimic those of many community and nosocomial respiratory infections, so the differential diagnosis is quite broad in scope. The initial workup should include routine laboratory and radiographic evaluations similar to those for workup of other, more common respiratory infections. A greater level of suspicion for SARS-CoV infection should be entertained based on travel or exposure history. Specific testing for coronavirus can be conducted through the health department.

Several outbreaks of SARS-CoV infection have occurred after exposure of patients or medical staff to a sentinel case or to a clinical specimen.83 Therefore, effective evaluation and management of suspected or proven cases of SARS-CoV disease must begin with a travel and occupational history, astute clinical observation, appropriate triaging, and patient isolation measures. Quarantine of persons who may be in the incubation period has proved useful in containing outbreaks.93 Contact and airborne precautions should be instituted and protective eyewear should be considered. Detailed guidelines for the diagnosis, isolation, treatment, and disposition of patients with suspected or proven SARS-CoV infection are continuously being updated by the WHO and the CDC. These guidelines are available at www.cdc.gov and www.who.int; local health officials also can be contacted for guidance.

Management. No therapeutic measures beyond supportive care have been shown to be clearly effective for the treatment of SARS-CoV infection.89,92,94 Patients manifesting signs and symptoms of lower respiratory tract infection should be treated with conventional antibiotic and supportive therapy, even if they are suspected of having SARS-CoV infection.

Disposition. It is not necessary to hospitalize all patients who are suspected to have been exposed to or have a respiratory syndrome that could be attributed to SARS-CoV infection. Persons well enough to be cared for at home should be placed in home quarantine with contact and air-borne precautions. Termination of quarantine precautions for suspected SARS-CoV infection should be done in consultation with public health officials.

Other Coronaviruses
Principles of Disease. Coronaviruses are agents of the common cold in adults and of lower respiratory tract disease in children. More recently, they have been implicated in diarrheal disease in children.

Clinical Features. Coronaviruses primarily cause upper respiratory tract disease in adults. Lower respiratory tract infections caused by coronaviruses occur uncommonly in adults and more commonly in children. They appear to cause diarrheal disease in children younger than 1 year of age.

Differential Considerations. Coronaviruses probably account for 15% of adult colds. Rhinoviruses account for most of the rest, with parainfluenza viruses, influenza viruses, respiratory syncytial viruses, adenoviruses, and enteroviruses also causing upper respiratory infections and colds. Rotaviruses, Norwalk viruses, and enteroviruses cause most viral cases of gastroenteritis in children.

Management and Disposition. Treatment of most coronaviruses is supportive only.

Parainfluenzaviridae
Parainfluenza Viruses
Clinical Features. The parainfluenza viruses are the most common causes of croup in children and, along with the respiratory syncytial virus (RSV), are the most common causes of lower respiratory tract infections that require hospitalization in infants.95

The virus is passed by way of the respiratory route, and hand–to–mucus membrane transmission is the likely mode of spread. The incubation period most often is 1 to 4 days, and the clinical picture is that of a febrile illness lasting approximately 4 days.

Infection with the parainfluenza viruses does not confer lasting immunity. Parainfluenza virus type 1 is the predominant cause of croup, or laryngotracheobronchitis, occurring during the autumn months in children younger than 3 years. Parainfluenza virus type 2 also is associated with croup, causes less morbidity than type 1, and often occurs in alternate years with type 1. Parainfluenza type 3 infections occur in the spring and are associated with bronchiolitis and pneumonia in infants younger than 1 year, similar to RSV. Parainfluenza virus type 3 also is associated with croup in children younger than 3, and with tracheobronchitis in older children. Parainfluenza type 4 is recovered less often but appears to be associated with mild respiratory illness. Severe croup or bacterial superinfection of laryngotracheitis may lead to respiratory compromise.

Differential Considerations. Viruses causing upper respiratory tract infection similar to that caused by the parainfluenza viruses include adenoviruses, rhinoviruses, influenza virus, RSV, echoviruses, coxsackieviruses, and coronaviruses. Identification of parainfluenza viral infection can be made by demonstrating a fourfold rise in antibody titer between acute and convalescent serum.

Management. Croup may be worse at night; mist inhalation often is helpful. Treatment with nebulized racemic epinephrine can be used to treat severe croup, but the relief it affords can be short-lived, and return to pretreatment state can be seen within 2 hours of therapy. Intramuscular steroids have been shown to be helpful, and their use has been associated with a decreased requirement for hospitalization of children with croup.95 A single dose of oral dexamethasone at 0.6 mg/kg has been shown to reduce return visits to a health care practitioner.96 The parainfluenza viruses can cause reinfection within months of the primary infection, so prevention of infection is unlikely to be feasible. More aggressive tracheal diseases, such as laryngotracheobronchitis and laryngotracheobronchopneumonitis, may be caused by viruses but most are often a result of superinfection with bacteria, including Staphylococcus aureus and group A streptococci.97

Respiratory Syncytial Virus
Principles of Disease. Infections with RSV occur worldwide, mostly in midwinter to late spring. Infants with pneumonia show marked inflammation in the interstitial tissue and alveoli of the lungs, whereas infants with bronchiolitis show less alveolar involvement but may exhibit marked changes in the bronchioles. Severe disease may result in obstruction of bronchioles with evidence of peripheral airway obstruction or emphysema. Transmission is through contact with respiratory secretions and probably also by hand-to-nose or eye droplet inoculation.

Infections caused by RSV account for the largest number of hospitalizations for respiratory infections in infants. Bronchiolitis and pneumonia, the most severe manifestations of RSV infection, commonly occur in children younger than 6 months. Children older than 1 year are less likely to have lower respiratory tract infection.98 Older children and adults commonly
have colds and cough, but older patients may have severe
disease.

Clinical Features. The average incubation time for RSV infec-
tions is 2 to 8 days. The most common manifestations are
bronchiolitis and pneumonia in infants; tracheobronchitis,
croup, and otitis media in young children; and upper respira-
tory infections in older children and adults. Bronchiolitis in
infancy may lead to an increased risk of asthma and the devel-
opment of chronic obstructive airway disease in later life. Fatal
disease can occur in immunocompromised infants.

The diagnosis of RSV infection can be made definitively by
culturing the virus or detecting RSV antigens from respiratory
secretions, nasal wash specimens, or nasopharyngeal or throat
swabs.

Differential Considerations. The syndromes associated with RSV
infections overlap those due to other upper and lower respira-
tory tract pathogens, including rhinovirus, parainfluenza and
influenza viruses, echoviruses, coxsackieviruses, and coronavi-
ruses. RSV infection can be presumptively diagnosed in an
infant with pneumonia or bronchiolitis when no bacterial
pathogens are noted. Noninfectious causes for hypoxemia in
infants, such as foreign-body aspiration and asthma, also must
be considered.

Management. Therapy of RSV infection is largely supportive.
For infants sick enough to be hospitalized, aerosolized ribavi-
rin has been shown to shorten the duration of illness and
ameliorate hypoxemia in normal infants. Corticosteroids have
not been shown to be beneficial. During the winter, high-risk
infants can be protected against RSV infection with monthly
infusions of human RSV immunoglobulin or with monthly
intramuscular injections of a monoclonal anti-RSV antibody
preparation. Severe disease may occur in immunocompro-
mised infants, and respiratory precautions are required to
prevent transmission from patient to patient and staff to
patient.

Mumps Virus

Principles of Disease. Mumps, or infectious parotitis, is an acute
viral illness characterized by fever, swelling, and tenderness of
the salivary glands, with the parotid gland most commonly
involved. Mumps occurs most commonly in the winter and
spring and, since the advent of widespread pediatric immuni-
ization, mostly in older children. The virus is spread by way of
the respiratory tract and through direct contact with the saliva
of infected people. The incubation period is 2 to 4 weeks, and
the disease is communicable from 1 week before to 9 days after
the onset of parotitis, with a period of maximal infectiousness
approximately 2 days before the onset of illness. One third of
cases are asymptomatic.

Clinical Features. Nonsuppurative parotid swelling is the hall-
mark of mumps; the swelling may be unilateral. Trismus
sometimes is a feature. In the first 3 days, the patient’s tem-
perature may range between normal and 40°C. The most
important but less common manifestations are epididymo-
orchitis and meningitis. Orchitis occurs in 15 to 25% of post-
pubertal male patients and usually is unilateral. Although
some degree of testicular atrophy is usual, the incidence of
sterility is very low, especially when the orchitis is unilateral.

More than 50% of patients with mumps have a lymphocytic
pleocytosis in the CSF, and hypoglycorrhachia is common;
symptomatic meningitis occurs in less than 10% of cases.
Encephalitis is uncommon, occurring in 1 in 6000 cases, and
is the major determinant of mortality. Congenital infection is
rare but may result in fetal loss if it occurs in the first trimester.
Rare complications of mumps include hydrocephalus,
deafness, transverse myelitis, Guillain-Barré syndrome, pan-
creatitis, mastitis, oophoritis, myocarditis, and arthritis.

Differential Considerations. In children, the diagnosis of mumps
is made by a history of infectious exposure and the presence
of parotid swelling and tenderness in association with consti-
tutional symptoms. Laboratory confirmation generally is not
required. Considerations in the differential diagnosis include
other viral infections and other causes of parotid swelling and
tenderness, such as bacterial parotitis or sarcoidosis.

A multisite outbreak of mumps was reported in the United
States in 2006, with almost 6000 reported cases. Because the
likelihood of infection was five times higher in persons who
had received only one dose of mumps vaccine as opposed to
those who had received two doses of the vaccine, updated
recommendations that all persons receive two doses of mumps
vaccine were introduced by the CDC’s Advisory Committee
on Immunization Practices.

Management. Treatment is supportive and should include an
analgies and an antipyretic agent. No data support the use of
steroids to prevent complications of or ameliorate the symp-
toms of orchitis in postpubertal men.

Contacts who have had no history of mumps or of previous
vaccination should be immunized. Because there is no risk in
vaccinating those who are already immune, serologic screening
to identify susceptible people is unnecessary. Long-lasting
immunity develops in more than 95% of recipients of the
vaccine. Among previously infected people, including those
who had asymptomatic disease, long-lasting and possibly life-
long immunity is possible.

Measles Virus (Rubeola)

Principles of Disease. Measles is a highly communicable viral illness
acquired as an infection of the respiratory tract. Generally, all
susceptible people exposed to an active case will acquire infec-
tion. After multiplication in the respiratory mucosa, the virus
spreads to regional lymphoid cells and then travels in the
bloodstream to leukocytes in the reticuloendothelial system.
The clinical manifestations appear after a second viremic
phase.

Before the availability of an effective vaccine in 1963,
measles was a ubiquitous disease. In 2006, measles accounted
for approximately 240,000 deaths globally; in view of higher
death rates in previous years, it is clear that great strides have
been made to decrease measles deaths in many areas of the
world. Measles continues to be a leading cause of death in
young children, especially those living in developing coun-
tries. Endemic measles in the United States has been
eradicated, although the disease continues to occur among
inadequately vaccinated persons who, in most instances, have
been exposed to the disease by someone who has been infected
abroad. Measles is a reportable disease, and the local health
authority should be contacted. Children should be kept out of
school for at least 4 days after the appearance of the rash.

Clinical Features. The incubation period of measles is 10 to 14
days. Cough, coryza, conjunctivitis, and fever precede devel-
opment of the characteristic rash by 2 to 4 days (Fig. 128-6A).
Pinpoint grayish spots surrounded by bright red inflammation
(Koplik’s spots) typically are found on the lateral buccal
mucosa before the appearance of the rash and are considered
pathognomonic for measles (see Fig. 128-6B). Discrete red
macular and papular lesions begin on the head and progress
downward over a period of 3 days to cover the entire body.
Laryngitis, tracheobronchitis, bronchiolitis, and pneumonia
may accompany the disease. Bacterial superinfections
occasionally delay recovery. A rare acute encephalomyelitis,
associated with a mortality rate of 25%, can complicate
recovery. Unlike rubella, measles acquired during pregnancy
is not teratogenic but may result in stillbirth or premature
delivery.
Subacute Sclerosis Panencephalitis

Principles of Disease. Subacute sclerosing panencephalitis (SSPE) is a degenerative disease of the brain caused by measles virus or a defective variant that persists in the CNS after primary measles. SSPE has virtually disappeared in the United States since the 1970s, approximately 10 years after measles vaccination began.

Clinical Features. SSPE is a subacute encephalitis involving both the white and the gray matter of the cerebral hemispheres and brainstem and follows 1 in 100,000 cases of measles. It generally occurs in patients with a history of an uncomplicated case of primary measles that occurred at a younger-than-average age. Five to 10 years later, subacute SSPE manifests with myoclonus and variable focal neurologic deficits. Progressive neurologic degeneration ensues, and death usually occurs within months to years of diagnosis.

Differential Considerations. The disease can resemble other degenerative neurologic disorders, but characteristic electroencephalographic changes and the detection of measles antibodies in the CSF and markedly elevated serum antibodies to measles will confirm the diagnosis.

Management. Treatment is supportive only.

Rhabdoviridae

Within the Rhabdoviridae family of viruses are two genera, Lyssavirus, containing the rabies and rabies-like viruses, and Vesiculovirus, containing the vesicular stomatitis and related viruses. Six lyssaviruses are known, but only the rabies, Duvenhage, and Mokola viruses are known to cause disease in humans. Rabies is discussed further in Chapter 129.

Vesicular Stomatitis Virus and Related Viruses

Vesicular stomatitis virus commonly infects wild and domestic animals and occasionally infects humans. Transmission is believed to be through insect bites. Vesicular stomatitis virus New Jersey type and vesicular stomatitis virus Indiana type produce an influenza-like febrile illness 1 to 2 days after exposure that lasts 4 to 7 days. Oral vesicular lesions occasionally have been noted.106 Accompanying disease manifestation can be nonspecific. Diagnosis can be made serologically. Treatment is supportive.

Filoviridae

Marburg and Ebola Viruses

Principles of Disease. Marburg and Ebola viruses cause a systemic febrile illnesses associated with multiorgan failure. Although the viruses have infected African green monkeys and cynomolgus monkeys, respectively, the infection is fatal to the monkeys, and the natural reservoir is unknown. Recent reports indicate a possible reservoir in certain bat species, but definitive proof is pending.107 Monkey-to-human and human-to-human transmission through contact with contaminated tissues or materials has been documented. Aerosol transmission has not been reported.

Clinical Features. The illness is of sudden onset 2 to 10 days after exposure to infected tissue or contact with contaminated materials. Headache, fever, myalgias, arthralgias, and lethargy are early signs. The cardinal sign is diffuse coagulopathy. With both Marburg and Ebola infections, documented mortality rates are greater than 90%. Human infection with Marburg virus was documented in Germany and the former Yugoslavia as a result of contact with imported green monkeys. Human outbreaks also have been documented in the Democratic
Republic of the Congo and Angola. To date, approximately 1850 cases of Ebola have been documented worldwide, with more than 1200 deaths. Differentiation of rising antibody titers. Diagnosis is made by isolation of the virus from blood or demonstration of rising antibody titers. 

Management. No vaccine exists; treatment is supportive.

Orthomyxoviridae

Influenza Virus

Principles of Disease. Influenza generally is a self-limited infection of the upper respiratory tract associated with fever, cough, coryza, sore throat, and malaise. Three types of influenza are recognized. Type A has been associated with most widespread epidemics and pandemics and is associated with most of the deaths caused by influenza. Influenza B causes regional or widespread epidemics every 2 to 3 years. Influenza C is associated with sporadic cases.

Clinical Features. The usual clinical disease caused by influenza begins 1 to 4 days after exposure to aerosol respiratory secretions. Clinical manifestations include fever accompanied by myalgias, coryza, conjunctivitis, headache, and a nonproductive cough. Patchy infiltrates can be seen on the chest radiograph. Signs and symptoms generally last only a few days, but fatigue and malaise may persist for weeks. The most common serious complications of influenza, particularly among the elderly and persons with chronic diseases, are pneumonia caused by influenza itself and pneumonia attributable to secondary bacterial infections. Rare complications of influenza infection include aseptic meningitis, pericarditis, and a postinfectious neuritis that resembles the Guillain-Barré syndrome.

Viral culture remains the “gold standard” modality for the laboratory diagnosis of influenza, but results often are not timely enough to aid in clinical decisions regarding therapy. Several rapid assays using nasal specimens for the diagnosis of influenza A and/or B are commercially available. Positive bedside test results are associated with increased use of antivirals and decreased use of antibiotics in both pediatric and adult patients.

Differential Considerations. The syndromes produced by the influenza viruses overlap with those produced by other viruses such as the parainfluenza viruses, RSV, adenoviruses, coronavirus, and echoviruses.

Management. General supportive measures will ameliorate the symptoms of influenza. The neuraminidase inhibitors zanamivir and oseltamivir have been approved for treating both influenza A and B. The dose of oseltamivir should be decreased to 75 mg once daily in patients with creatinine clearance less than 30 mL/min. Zanamivir or oseltamivir should be administered within 2 days of onset of symptoms if efficacy is to be expected. Vaccination is recommended yearly for all children 6 months to 4 years of age, adults older than 50 years, and persons at high risk for significant morbidity or death from influenza; these include immunosuppressed patients, those with chronic illnesses, and pregnant women. Vaccination is also recommended for health care workers and persons who are household contacts of infected persons younger than 5 or older than 50 years. In addition, the CDC recommends annual vaccination for all persons “who want to reduce the risk of becoming ill with influenza or of transmitting influenza to others.” Aspirin and aspirin-containing products should be avoided, especially among children and adolescents, particularly during influenza epidemics, because of the association between the use of aspirin during a bout of influenza and the subsequent development of Reye’s syndrome.

A highly pathogenic strain of avian influenza virus, H5N1, was first reported in a farmed goose in China in 1996. Since then, the virus has spread among wild birds and poultry across the Asian continent into large parts of Europe and some areas in Africa. H5N1 has yet to be reported among fowl in the Americas or Australia. Human disease attributable to highly pathogenic avian influenza virus has been reported in several countries of Asia, the Middle East, and Africa. Although direct human contact with affected birds appears to be the major mode of transmission, human-to-human spread has been documented, and cases of unexplained transmission indicate that environment-to-human transmission may be possible. The incubation period is less than a week. Clinical disease can range in severity from an asymptomatic or mildly symptomatic viral syndrome to a highly fulminant and deadly illness. Highly pathogenic avian influenza virus infection should be suspected in a person who is at risk for contracting the illness because of exposure to a known disease reservoir and who has a progressive respiratory illness. Public health officials should be contacted if the disease is suspected, and full infection control measures should be instituted. Early antiviral therapy with oseltamivir at high doses (150 mg twice a day) and possibly with amantadine or rimantadine is recommended, along with appropriate supportive care. Oseltamivir-resistant H5N1 has been described. PEP and the use of antiviral medication for asymptomatic persons during an outbreak should be prescribed in consultation with disease experts. To date, there have been 385 laboratory-confirmed cases with 243 deaths reported by the WHO; actual morbidity and mortality figures probably are higher. Despite aggressive public health measures, such as culling of affected fowl populations, many experts feel that avian influenza can become a serious global pandemic.

Bunyaviridae

California Encephalitis and Bunyavirus Hemorrhagic Fevers

Pathophysiology and Clinical Findings. California encephalitis viruses, including the La Crosse and Johnson Canyon viruses, are transmitted by mosquito bites, predominantly in the northern United States in the summer and fall. Approximately 100 cases are reported yearly. Infection is mostly asymptomatic, but the mortality rate associated with the encephalitis is approximately 1%. Bunyaviridae family of viruses includes the Crimean-Congo hemorrhagic fever virus, the Rift Valley fever virus, and the hantaviruses, a genus of viruses that cause a hemorrhagic fever with renal syndrome.

Rodents carry hantaviruses; the disease is transmitted by way of aerosols from infected rodent excretions. Hantaviruses can be divided into Old World and New World varieties. Old World hantaviruses, which predominate in Europe and Asia, tend to cause milder disease and have been associated with hemorrhagic fever with renal syndrome. More than 100,000 cases occur in Asia and Europe yearly, and the mortality rate is approximately 6%. New World hantaviruses occur mainly in the Americas. In 1994, a previously unknown New World hantavirus was found to cause a pulmonary syndrome associated with tachypnea, hemoconcentration, thrombocytopenia, and leukocytosis. Cases occurred predominantly in the southwestern United States and were associated with a mortality rate higher than 50%. The disease was transmitted from the deer mouse, Peromyscus maniculatus. The virus has been designated the sin nombre virus.
Several other hantavirus species have been identified in central and south America that also have been associated with hantavirus pulmonary syndrome or hantavirus cardiopulmonary syndrome. Rift Valley fever virus is carried by a mosquito and generally produces a nonspecific febrile disease. Up to 100,000 cases occur yearly in Africa. In some patients, a severe retinitis develops that may lead to blindness. Congo-Crimean hemorrhagic fever is a severe, rare, tick-transmitted disease that occurs in Africa and Asia, with a mortality rate approaching 50%.

Management. Treatment of all of these diseases is supportive. The CDC provides intravenous ribavirin for investigational use.

Arenaviridae

Lymphocytic Choriomeningitis, Lassa, and Arenaviral (Hemorrhagic Fever) Viruses

Principles of Disease. The arenaviruses are carried by parasites of rodents and probably are passed to humans from contact with infected rodent urine. Four arenaviruses are known to cause human disease: Lymphocytic choriomeningitis (LCM) virus causes a meningoencephalitis that may be severe but is rarely fatal. Junin and Machupo viruses, from Argentina and Bolivia, respectively, and the Lassa virus, from Africa, cause severe and often fatal hemorrhagic fevers.

Clinical Features. LCM virus infection commonly is transmitted from person to person. LCM occurs in the Americas, Europe, and Asia and usually is passed from house mice, pet hamsters, or laboratory animals. Influenza-like symptoms follow a 7- to 10-day incubation period and generally are followed by complete recovery. Meningitis may ensue, but even severe cases are associated with good recovery. Orchitis and parotitis may accompany the disease. LCM still poses a hazard in research settings in the United States.

Lassa fever is a highly contagious disease occurring in West Africa, with a case-fatality rate of up to 25% in hospitalized patients. The vector is a common rat species. Transmission is thought to occur by contact with the rats or their droppings or by contact with infected persons. In certain areas of Africa, the rate of seropositivity in the general population can be as high as 55%. A gradual onset of fever and malaise after an incubation period of 6 to 21 days is characteristic. The disease is mild or asymptomatic in up to 80% of infected persons, but in approximately 20%, it causes high fever, exudative pharyngitis, and diffuse pain (headache, chest pain, abdominal pain) and often is accompanied by vomiting and diarrhea. Worsening disease is characterized by myocardial failure, mucosal bleeding, coma, and death. Pneumonitis and respiratory distress may develop. Early lymphopenia followed by neutropenia and elevated transaminases is associated with a poor prognosis. Argentine hemorrhagic fever, caused by the Junin virus, causes a skin rash and petechiae and is more likely to be hemorrhagic than Lassa fever. The disease manifests after a 7- to 10-day incubation period with fever, malaise, anorexia, and myalgias. Petechiae and gastrointestinal bleeding occur between days 4 and 6, and shock may follow. Case-fatality rates range up to 30%. Bolivian hemorrhagic fever, caused by Machupo virus, is similar to Argentine hemorrhagic fever but occurs much less commonly.

Differential Considerations. LCM virus infection can resemble other viral causes of meningitis or encephalitis. The diagnosis of arenavirus infections requires a fourfold rise in antibody titer.

Management. Only supportive care is required for LCM. Ribavirin has been used effectively to treat Lassa fever and can result in a fivefold decrease in mortality. Argentine hemorrhagic fever and possibly Bolivian hemorrhagic fever can be successfully treated with convalescent plasma from a recovered patient. Prevention of arenavirus infections is best accomplished by controlling the infected vectors. Special care must be taken to prevent person-to-person spread of Lassa fever.

Retroviridae

Three subfamilies are described in family Retroviridae: the type C oncoviruses (human T-cell leukemia virus types I and II [HTLV-I, HTLV-II]), the lentiviruses (e.g., human immunodeficiency viruses types 1 and 2 [HIV-1, HIV-2]), and the spumaviruses. Only the oncoviruses and lentiviruses have been shown to cause disease in humans.

Type C Oncoviruses

The demonstration that RNA could be transcribed into DNA by the reverse transcriptase in RNA tumor viruses laid the groundwork for the discovery of human retroviruses. In approximately 1% of people infected in childhood with HTLV-I, adult T-cell leukemia develops later in life. HTLV-I also has been associated with tropical spastic paraparesis, also known as HTLV-I-associated myelopathy. HTLV-II was isolated in 1982 and found to be associated with a T-cell variant of hairy cell leukemia.

Human Immunodeficiency Virus

HIV is a slow virus, or lentivirus, related to animal viruses such as the visna virus and feline leukemia virus. A full description of HIV and AIDS is presented in Chapter 130.

Picornaviridae

The designation for family Picornaviridae is derived from pico, meaning “very small,” and RNA, their nucleic acid type. Picornaviridae includes two viruses that infect humans: the enterovirus, containing 67 recognized species (including the polioviruses, coxsackieviruses, echoviruses, and hepatitis A virus), and the rhinovirus, with more than 100 human species that cause illness in humans.

Poliovirus

Principles of Disease. Poliomyelitis is an acute viral infection that ranges in severity from an inapparent infection to a nonspecific febrile illness to aseptic meningitis to severe paralysis and death. Since the introduction of polio vaccination in the United States, only a handful of cases of paralytic poliomyelitis have been diagnosed each year, and most of these cases are either imported or vaccine-associated. Since oral polio vaccine (OPV) was replaced by inactivated polio vaccine (IPV) in 2000, there have been no reports of vaccine-associated paralytic polio in the United States, although rare cases of imported paralytic polio have been reported.

Poliovirus is transmitted during close contact; transmission both by the fecal-oral route and through contact with respiratory secretions has been documented. Susceptibility to poliovirus is universal, but paralytic infections are rare, increasing in incidence with age at the time of infection. At least 95% of infections are inapparent or asymptomatic.

Clinical Features. With paralytic poliomyelitis, the usual incubation period is 7 to 14 days. The disease in children usually is biphasic, with a brief viremic phase lasting 1 to 3 days. After recovery for 2 to 5 days, an abrupt onset of headache, fever, malaise, vomiting, and CSF pleocytosis ensues. This meningitic phase lasts for 1 to 2 days before the beginning of
weakness and flaccid paralysis. Bulbar paralytic poliomyelitis involves paralysis of the muscle groups innervated by the cranial nerves. The most important complications of paralytic poliomyelitis are respiratory, especially respiratory failure caused by paralysis of the respiratory muscles, aspiration pneumonia, and pulmonary embolism. Myocarditis may rarely occur. Muscular paralysis usually lasts for only 1 to 3 days after its onset. A postparalytic paralysis syndrome has been described in which neuromuscular weakness recurs several decades after resolution of the acute poliovirus infection.  

**Differential Considerations.** Paralytic poliomyelitis usually can be recognized on clinical presentation. Other enteroviruses can cause a similar syndrome. Guillain-Barré syndrome and post-encephalitic syndromes may resemble paralytic poliomyelitis. Considerations in the differential diagnosis for nonparalytic encephalitic syndromes may resemble paralytic poliomyelitis. The definitive diagnosis is made by isolation of the virus from fecal material or respiratory secretions.

**Management.** Specific antiviral treatment for poliomyelitis is not available. Management is supportive, and reporting to local health authorities is mandatory. In the acute phase of paralytic poliomyelitis, patients require hospitalization. Routine vaccination in the United States has dramatically reduced the number of cases of paralytic poliomyelitis. The Salk IPV is recommended for most indications in the United States. IPV has the advantage of preventing paralytic disease, but it does not protect susceptible contacts by secondary spread. The Sabin OPV protects susceptible contacts, but it is associated with vaccine-associated cases of paralytic disease. In 2000, the CDC recommended that all U.S. children receive four doses of IPV at ages 2, 4, and 6 to 18 months and 4 to 6 years.

**Coxsackieviruses, Echoviruses, and Other Enteroviruses**

**Principles of Disease.** The enteroviruses are spread from person to person by the fecal-oral route. As with poliovirus, inapparent infections greatly outnumber symptomatic cases.

All enteroviruses enter the body through the oropharynx and multiply in the tissues around the oropharynx. The viruses are stable in acid conditions and are capable of passing through the stomach to the intestines.

**Clinical Features.** Most enteroviral infections are inapparent. The most common clinical presentation is that of a nonspecific febrile illness. Young children may be hospitalized with enteroviral fevers that simulate bacterial sepsis. Coxsackievirus B and some of the echoviruses may cause severe perinatal infection associated with fever, meningitis, myocarditis, and hepatitis.

Febrile diseases with rashes often are associated with enteroviruses. Exanthsms resembling that of rubella occurring during the summer months have been seen with the echoviruses and coxsackie A viruses. Vesicular lesions are seen, such as with the hand-foot-and-mouth syndrome caused by some coxsackieviruses A and B. Herpangina, a specific disease characterized by a vesicular rash on the cheeks and soft palate and associated with fever, sore throat, and severe pain on swallowing, is caused by the coxsackievirus A. Roseola-like exanthems and petechial exanthems also are associated with coxsackievirus and echovirus infections.

The enteroviruses are the most common causes of viral meningitis. The course generally is benign, but enteroviral infections often can be confused with a bacterial process, particularly in the acute phase, when CSF analysis may show a neutrophil predominance. Coxsackie B viruses are strongly associated with myocarditis, although echoviruses and coxsackie A viruses also can cause the disease. Severe cases may lead to dysrhythmias, heart failure, or death.

Enteroviruses cause upper respiratory tract infections similar to other causes of the common cold. Interstitial pneumonias also can occur. Pleurodynia (Bornholm’s disease—the “devil’s grippe”) generally is associated with the coxsackie B viruses. This disease involves the intercostal muscles and can last for several weeks.

Other proven or suggested associations with the enteroviruses and disease include enterovirus 70 and acute hemorrhagic conjunctivitis; coxsackieviruses and echoviruses with diarrhea and gastroenteritis; coxsackieviruses and echoviruses with hemolytic-uremic syndrome; and enteroviruses with acute myositis. Other possible associations include chronic cardiomyopathy, aortitis, hepatitis, pancreatitis, orchitis, diabetes mellitus, lymphadenopathy, a mononucleosis-like syndrome, and infectious lymphocytosis. A progressive, dementing, chronic meningitis associated with enteroviruses has been reported in persons with common variable immunodeficiency syndrome.

**Management.** No specific treatments are available for infections caused by the enteroviruses. Care is supportive. Vaccination against poliovirus and hepatitis A is recommended, and immune serum globulin also can prevent the acquisition of hepatitis A infection.

**Hepatitis A Virus**

The hepatitis A virus is now classified among the picornaviruses. Hepatitis A is discussed in Chapter 88.

**Rhinovirus**

**Principles of Disease.** Rhinoviruses are the most common cause of the common cold. More than 100 strains exist. Rhinovirus transmission generally occurs primarily by hand contact and through inoculation of the eye or nasal mucosa and less commonly by aerosolization of respiratory secretions. Viral replication probably occurs on the epithelial surface of the nasal mucosa.

**Clinical Features.** After a 1- to 4-day incubation period, the usual signs and symptoms of rhinoviral infection occur, including nasal obstruction, sneezing, sore throat, cough, and malaise. Severe tracheobronchitis and pneumonia occur rarely. Fever and lower respiratory tract infections are more common in children than in adults with rhinovirus infections.

**Differential Considerations.** Other respiratory pathogens such as coronavirus, RSV, parainfluenza viruses, influenza viruses, adenoviruses, and enteroviruses can produce clinical syndromes similar to those produced by the rhinoviruses. The rhinoviruses in general cause less morbidity than that typical for the parainfluenza viruses and RSV. Definitive diagnosis is made by the demonstration of a rise in antibody titer.

**Management.** Treatment is aimed at relieving symptoms. Routine vaccination appears to be an unlikely prospect because of the number of serotypes. Because hand-to-face inoculation appears to be the predominant means of transmission, frequent hand washing during epidemic periods may decrease the spread of rhinovirus infections.

**Caliciviridae**

**Caliciviruses and Astroviruses**

**Principles of Disease.** Caliciviruses and astroviruses are small RNA viruses that have been implicated in outbreaks of gastroenteritis, predominantly in children. The noroviruses (which include the Norwalk virus) and the sapoviruses are caliciviruses. The sapoviruses cause gastroenteritis in children, whereas the noro-
viruses affect people of all ages. Norwalk virus may peak in the winter months and often is associated with outbreaks in populations living in close quarters (such as cruise ships).135

**Clinical Features.** The incubation period probably is 1 to 4 days, and the disease lasts from 1 to 3 days. The disease is generally mild and accompanied by low-grade fever. Vomiting appears to be less common with astroviral disease than with calicivirus infections. One third of outbreaks of gastroenteritis can be attributed to a Norwalk virus–like agent. Diarrhea induced by these agents is associated with transient fat malabsorption. Outbreaks have occurred in schools and other institutions and through the ingestion of inadequately cooked shellfish. The mode of transmission is unknown but probably is by the fecal-oral route. Vomiting and diarrhea occur along with myalgias, malaise, headache, and low-grade fever. Severe diarrhea is rare and stools are not bloody.

**Differential Considerations.** Other causes of gastroenteritis associated with a similar syndrome include adenoviruses, enteroviruses, and coronaviruses. Electron microscopy can make the definitive diagnosis.

**Management.** Treatment is supportive. The gastroenteritis generally is self-limited and resolves without specific therapy. Oral rehydration solutions generally are adequate; rarely, intravenous therapy is required.

### Unclassified Viruses

**Hepatitis E Virus**

Hepatitis E virus is an RNA virus that has been identified as a cause of enterically transmitted hepatitis. It has been implicated as a cause of fulminant hepatitis in pregnant women.

**Prions**

**Principles of Disease.** The coined term prion (proteinaceous infectious particle [-on]) refers to the transmissible agent putatively responsible for a group of chronic neurodegenerative disorders sharing certain pathologic features. Prions have not been found to contain nucleic acid.136,137 Other terms for these agents have included unconventional virus and virino. The group of diseases caused by these agents, also referred to as slow virus infections or simply slow infections, includes Creutzfeldt-Jakob disease (CJD), kuru, and the Gerstmann-Straussler syndrome. Bovine spongiform encephalopathy in cattle, or new-variant CJD in humans, occurred primarily in the United Kingdom in the early 1990s, probably as a result of a change in the practice of offal rendering.138 By 2001, a few cases had been found elsewhere in Europe but not in the United States. Fortunately, owing to changes in handling meat byproducts and cattle feed, the incidence of bovine spongiform encephalopathy appears to be decreasing.

A characteristic feature of these diseases is the lack of any inflammatory response. A reactive astrocytosis to the presence of the virus occurs in the CNS, accompanied by neuronal vacuolation resulting in spongiform encephalopathy.

**Clinical Findings.** CJD is a rare disease, usually manifesting in late middle age with a progressive dementia combined with ataxia and myoclonic jerking. Distribution is worldwide and sporadic. CJD has been transmitted from person to person by direct inoculation (e.g., in corneal transplants and dura mater grafts). Kuru and the Gerstmann-Straussler syndrome manifest as cerebellar syndromes, with dementia occurring late in the course of the disease. Kuru has been associated with cannibalism confined to a few tribes in the highlands of New Guinea.139 With both CJD and kuru, progression is rapid, with death usually occurring in less than 1 year. The Gerstmann- Straussler syndrome follows a more slowly progressive course of up to 10 years.

**Differential Considerations.** CJD can be confused with Alzheimer’s disease or other slowly progressive dementing diseases. Other diseases to consider in the differential diagnosis include multi-infarct dementia, nutritional deficiency syndromes, and primary brain tumors. CT and magnetic resonance imaging scans usually are nondiagnostic, but the electroencephalogram often shows changes characteristic of CJD.

---

**KEY CONCEPTS**

- New vaccines have been introduced against rotavirus, HPV, and herpes zoster virus.
- Cases of highly pathogenic avian influenza (due to the H5N1 strain of the virus) have been documented.
- Patients who have primary genital herpes or severe or frequent recurrences of infection and patients who are immunosuppressed and have continuous infections should receive acyclovir, famciclovir, or valacyclovir. Herpes simplex encephalitis constitutes a medical emergency requiring rapid diagnosis and treatment with intravenous acyclovir.
- Patients with herpes zoster that is disseminated or that involves more than one dermatome should be treated with intravenous acyclovir.
- West Nile virus infection most severely affects the elderly. Treatment is supportive; management of the disease requires reporting to public health authorities and control of vector mosquito populations.
- The presentation of SARS-CoV infection mimics that of other community-acquired or nosocomial respiratory infections. Its recognition depends on obtaining a good possible contact history; its control requires prompt initiation of isolation procedures.
- Young children should be routinely vaccinated against influenza A. People at higher risk of becoming infected, those in whom considerable morbidity can be expected, or those who are likely to transmit influenza A to at-risk groups should receive an influenza vaccine annually. In patients with symptoms of influenza, the duration of illness may be shortened by 1 to 2 days if treatment with neuraminidase inhibitors is initiated within 48 hours after symptom onset.

The references and suggested reading list for this chapter can be found online by accessing the accompanying Expert Consult website.
Rabies is arguably the oldest infection known to humans. The term rabies comes from the Sanskrit rabhas, which means “to do violence.” The Eshmun Code of Babylon, from the 23rd century BCE, contains one of the earliest regulations regarding rabies: A fine of 40 shekels was levied on the owner of a dog that killed another man through a rabid bite.1,2

Today, rabies is a huge public health problem in Third World countries; according to the World Health Organization (WHO), an estimated 55,000 deaths from rabies occur annually worldwide, 31,000 of these in Asia and 24,000 in Africa3 (Fig. 129-1). In the United States and Puerto Rico, however, human rabies is extremely rare as a result of a successful vaccination program for domestic animals that began in 1947. In the pre-vaccination era, approximately 40 human cases were reported each year. By contrast, during 2006 only three cases of human rabies were reported to the Centers for Disease Control and Prevention (CDC).4,7

**EPIDEMIOLOGY**

Although it is believed that any mammal can contract rabies, species within the orders Carnivora and Chiroptera (bats) are considered to be the most important reservoirs for maintenance and transmission of the disease.8-10 Worldwide, dogs are the most commonly infected animal and the most common source of rabies in humans. Dogs are the primary reservoir of rabies in Asia and in many developing countries of Africa, although since 2003, South America has reported more human deaths from wildlife bites than from dog bites.11 In Europe, Canada, and the Arctic and sub-Arctic regions, the principal carrier is the fox, and in Puerto Rico, it is the mongoose. Jackals are the main wildlife reservoir of rabies in Africa. Bats are an important source of rabies in North and South America and Mexico. Bats carrying rabies-related lyssaviruses also are found in Africa, Europe, and Australia.

In the United States, more than 90% of all cases of rabies occur in wild animals; the principal reservoirs are raccoons, bats, skunks, and foxes.7 In Mexico, the primary reservoirs are dogs and bats, while other reservoirs include the coyote (likely a spillover from dog raccoons), the gray fox (overlapping with the same species in the United States), and the skunk.12

Rabies in terrestrial animals occurs in discrete geographic regions where the virus is transmitted primarily among members of a single species (Fig. 129-2). Each species and location are associated with a unique variant of the rabies virus. In the United States, for example, rabies is endemic in raccoons along the Eastern seaboard. A different strain of virus is carried by skunks in the north central states; two additional distinctive strains are carried by the skunks in the south central states and rabid skunks endemic to California. Arctic and red foxes in Alaska carry another rabies variant. As a result of their migration across Canada, the red foxes of New England have the same rabies virus variant. Two gray fox reservoirs with a unique rabies virus variant are found in Arizona and in Texas. For many years, a distinct variant was found in the dog-coyote mix along the Texas-Mexico border, although no transmission of dog-coyote rabies variant has been documented since 2004, supporting the contention that no canine rabies variant has been in circulation in the United States for the past 2 years.9

Wherever rabies is endemic, other wild carnivores or domestic animals may become infected by contact with the endemic species and will carry the viral variant of the endemic species (spillover). The increase in skunk rabies in New England is largely attributable to the raccoon epizootic that has occurred there, although some of the skunk rabies has resulted from spillover from foxes. Although raccoons have never been transmitted from a rodent or lagomorph (rabbit or hare) to humans, these animals do contract rabies, usually from the terrestrial reservoir in their region. Most rodent cases are found in larger rodents, such as groundhogs or beavers. In the United States, infected groundhogs generally are found in the areas in which raccoon rabies is endemic.5 Rabid bats are ubiquitous throughout the United States and North America and account for 24% of all cases of rabies in U.S. animals, making them the second most common source of rabies in the United States; 6% of all bats submitted to state health departments tested positive for rabies in 2006. The only U.S. state that remains rabies-free is Hawaii, where there are no rabid bats or rabid terrestrial animals.5 As with terrestrial reservoirs, bats carry viral variants unique to that species, but the geographic associations are less distinct, relating only to where a particular species of bats makes its home (Fig. 129-3). Rabid bats are capable of infecting terrestrial animals, as well as humans, in any area of the mainland United States. However, spillover (in which these animals carry and transmit the bat virus variant) appears to be extremely rare.13

The association of a unique raccoon virus variant with a particular species and locale makes it possible to determine the
source of rabies in areas or species that previously were rabies-free. Additionally, antigenic typing permits identification of the source of human infections when the animal contact is unknown.14,15

Wild and Domestic Animal Rabies

Since the 1950s, rabies in U.S. domestic animals has significantly decreased, but the population of rabid wild animals has actually increased (Fig. 129-4). In 2006, rabies was reported in 6940 wild animals, compared with 4742 cases in 1988.3,16 The primary reservoirs are raccoons, bats, skunks, and foxes (Fig. 129-5). In the 1960s and 1970s, a majority of cases of wildlife rabies were found in skunks in the United States. However, in the late 1970s, an epizootic among raccoons began in the mid-Atlantic states and spread north and south to cover the entire eastern seaboard; in 2006, more cases of wildlife rabies in the United States were attributable to raccoons than to any other wild animal (n = 2615, or 37.7%), with skunks now representing the second most populous (22%) of the rabid animal population. The source of this epizootic appears to be the inadvertent translocation of rabid raccoons from the southeastern states to the mid-Atlantic region by humans to stock the area for hunting, as evidenced by the fact that rabid raccoons seen first in the mid-Atlantic states, and now along the entire East Coast, carry the same viral variant as those in the southeastern states. The population has spread geographically north and westward. Raccoon rabies is now enzootic in all of the eastern coastal states as well as in Alabama, Ohio, Tennessee, Pennsylvania, Vermont, and West Virginia. The first rabid raccoon in Canada was found in Ontario in 1999; 89 rabid raccoons were reported in 2001, but the population declined to 26 cases in 2002 after wildlife control measures were instituted: In 2006, only five cases in raccoons were reported.3,17,18 A smaller epizootic of coyotes began in the early 1990s in southern Texas; three rabid coyotes were reported in 1990 and 71 in 1993, but the population has since returned to low levels. No instances of dog-coyote rabies have been reported since 2004 in the United States.3,19,20

The number of rabid domestic animals has remained relatively constant for the last decade and accounted for approximately 8% (547 cases) of all rabies in the United States.3 In 2006, Pennsylvania reported the largest number of domestic rabid animals (72 cases), followed by Virginia (62 cases). Cats are the domestic animal most frequently reported as rabid, accounting for approximately 58% of all cases of domestic animal rabies. There were 318 cases of rabies in cats in 2006, compared with 192 in 1988.21 Approximately 80% of rabid cats were reported from states in which raccoon rabies is present, whereas cases in the central plains states were a result of spill-
Figure 129-3. Reported U.S. cases of rabies in bats by county, 2006. Rabies in bats accounted for 24% of all cases of animal rabies. Texas reported the largest number of cases in bats, followed by California and New York. (From Blanton JD, Hanlon CA, Rupprecht CE: Rabies surveillance in the United States during 2006. J Am Vet Med Assoc 231:540, 2007.)

Figure 129-4. Cases of animal rabies, 1955 to 2006. Rabies vaccination campaigns in the 1940s and 1950s resulted in a substantial decrease in rabies in domestic animals. Similarly, elimination of the dog-coyote rabies virus variant and reduction in the gray fox virus variant also have been documented. (From Blanton JD, Hanlon CA, Rupprecht CE: Rabies surveillance in the United States during 2006. J Am Vet Med Assoc 231:540, 2007.)

over from rabid skunks. In 2006, there were 79 rabid dogs in the United States; in 1988, there were 128. Texas, Georgia, and North Carolina reported the largest number of cases of dog rabies in 2006. Dog rabies also appears to parallel the distribution of rabid skunk rabies in the south central states and of gray fox rabies in Texas. The number of rabid cattle decreased by 11.8% (82 total cases) in 2006; distribution closely follows that of skunks in the central and midwestern United States and raccoons in the Northeast and mid-Atlantic regions.

The median age of rabid cats and dogs is 1 year; most have not been vaccinated or have received only one vaccination. Dogs and cats generally are infected with a strain of rabies virus that is endemic in the terrestrial reservoir in their geographic area. Puerto Rico reported a total of five cases of cat rabies in 2005 and 2006, which is a presumed spillover from mongoose variant. Most owners are unaware of their pets' exposure to wild animals that may carry rabies.

Rabies in Humans

Human cases of rabies in the United States remain low owing to effective animal vaccination programs and availability of human vaccines and immunoglobulins. Between 1996 and 2006, 33 cases of human rabies were reported to the CDC, 21 of which were acquired from animal sources in the United States. One case was associated with the raccoon variant from the eastern United States, one case was due to a dog-mongoose variant in Puerto Rico, and the rest were associated with bats. Four cases were in transplant recipients, from a donor who died of an unknown encephalopathy, only later identified as rabies. For most bat-associated cases, a history
of bat contact was discovered only during hospitalization or determined after the patient’s death, when antigenic analysis of the rabies virus infecting the victim revealed a bat variant. In more than one half of the cases, the victim was known to have had contact with a bat, although no rabies prophylaxis was sought. In most other cases, a history of bat exposure was lacking. Although rabies has been found in most of the bat species in the United States, the species most frequently identified with “cryptic” bat rabies in humans is the silver-haired, eastern pipistrelle bat, a solitary, reclusive, tree-dwelling species that is seldom found in buildings and is thought to be rarely encountered by humans. The viral strain associated with this species appears to replicate better and at tree-dwelling species that is seldom found in buildings and is

Figure 129-5. Relative proportion of cases of rabies in animals in the United States, 2006. Data for other domestic and wild animals are not shown in the pie chart. Numbers may not add up to 100% because of rounding. A total of 2,615 cases of rabies in raccoons were reported in 2006, representing an increase after 3 years of decline. Increases also were reported among bats, skunks, and foxes in 2006 compared with 2005. (From Blanton JD, Hanlon CA, Rupprecht CE: Rabies surveillance in the United States during 2006. J Am Vet Med Assoc 231:540, 2007.)

**PRINCIPLES OF DISEASE**

Rabies is caused by a neurotropic rhabdovirus of the genus *Lyssavirus* (from the Greek word *lyssa*, which means frenzy). Animals are the natural reservoir for the virus; animals that are infected with the virus become sick and die, usually within 3 to 9 days of the time they first begin secreting virus in the saliva. Insectivorous bats may live 10 days; vampire bats, possibly longer. Some evidence suggests that dogs can become asymptomatic carriers, but transmission of disease from such an animal to humans has never been documented. A survey of rabid dogs in the United States in 1988 found that all died within 8 days of becoming ill; the median time until death was 3 days.

Animals are capable of transmitting rabies once they start secreting virus in saliva. Most animals with rabies will be sick before excretion of virus, but some may not become ill for several days after virus can be found in their saliva. The classic picture of a mangy dog foaming at the mouth and wildly running through town is not often seen; clinical signs are invariably present but frequently are more subtle. Indeed, less than one half of cases of rabies in domestic animals are initially recognized by veterinarians. The animal may display aggressive behavior, ataxia, irritability, anorexia, lethargy, or excessive salivation; cats are more likely than dogs to demonstrate aggressive or irritable behavior. In a wild animal, however, what may be most apparent is a change in instinctive behavior—for instance, a nocturnal animal may be observed boldly walking through downtown in broad daylight. An unprovoked bite from a domestic animal may be a sign of rabies; however, humans, especially children, often inadvertently provoke a pet by cornering it or competing with it for its natural prey.

Rabies is transmitted when the virus is introduced into bite wounds or open cuts in skin or onto mucous membranes. Almost all documented cases of human rabies have been transmitted by a bite. The risk of transmission by a bite is approximately 50 times that with a scratch; rabies also has been contracted by recipients of corneal and organ transplants from infected donors. In animals, rabies is known to be transmitted transplacentally and has been shown to be transmissible experimentally by aerosol under artificial and extreme conditions and by ingestion. Other than through transplants, human-to-human transmission has never been confirmed, although two possible cases in family members of rabies victims in Ethiopia that were not laboratory-confirmed have been described. Rabies virus has never been isolated from blood.

The virus replicates in muscle cells near the site of the bite, remaining at the site of inoculation for most of the incubation period before entering the peripheral nerve by way of the neuromuscular junction, and then rapidly ascending by retrograde conduction along peripheral nerves to the central nervous system. It is estimated that the virus travels along motor and sensory axons at a rate of approximately 8 to 20 mm/day and has a predilection for the thalamus, basal ganglia, and brainstem. Once in the CNS, the virus creates the well-known Negri bodies in the nuclei of neurons, where it manufactures copies of itself that then bud out to infect other neurons. Virion then is transported through the peripheral nerves by antegrade conduction to the salivary glands, where it can be excreted and transmit the disease to a new victim through a bite.

Of interest, the virus does not destroy the neurons; in fact, it prevents cell apoptosis. How rabies actually kills humans, therefore, has been something of a mystery. Recent theories suggest that in the presence of the rabies virus, there is an outpouring of cytokines and proinflammatory molecules that modify electrical activity in the brain and affect the hypothalamic-pituitary axis and serotonin metabolism, causing the clinical symptoms. The immune reaction recruits T and B cells and results in more cytokine and nitric oxide production. Eventually, cells are depleted of all metabolic pools and cell death then occurs. Thus, the body’s own immune reaction may be the actual cause of death. Clinical support for this theory is that persons who have intact T cell immunity are more likely to have encephalitic rabies and die quickly, whereas those with impaired immunity are more likely to have paralytic rabies and live longer.

The risk of developing rabies after a bite ranges from 5 to 80% and depends on the type of biting animal, the severity of the exposure, and the location of the bite. All of these factors contribute to the ultimate mortality rate in unvaccinated victims.

**CLINICAL FEATURES**

Clinical rabies progresses through five stages: incubation, prodrome, acute neurologic illness, coma, and death. The incubation period (bite to first symptom) typically is 20 to 90 days but has been documented to be as short as 10 days and as long as 7 years. Bites on the head and neck result in disease with
a shorter incubation period (as short as 15 days) than that for bites on the trunk or lower extremity, most likely because of the rich peripheral nerve supply in the head and neck area.35 The mortality rate is lower among victims with lower-extremity bites.36

The prodromal phase can last a day to a week. The clinical manifestations usually are nonspecific and range from numbness or pain at the bite site to generalized flulike signs and symptoms, such as low-grade fever, nausea, vomiting, headache, myalgia, sore throat, runny nose, and malaise. The acute neurologic syndrome occurs after the prodromal phase and will vary according to the type of rabies that is being manifested. Full-blown rabies has two classic forms: the “furious” or encephalitic form and the paralytic or “dumb” form; another, more recently identified form, “nonclassic,” also has been described.46 Encephalitic rabies is the far more common of the classic forms and is manifested by agitation, hydrophobia, fluctuating consciousness, and extreme irritability; periods of hyperexcitability fluctuate with lucidity or lethargy. Vital signs often are abnormal, with tachycardia, tachypnea, and fever. Hyperactivity is aggravated by light, noise, thirst, and fear. Hydrophobia, so named because of patients’ inability to swallow, appears to result from an exaggerated respiratory tract protective reflex that results in a violent, jerky contraction of the diaphragm and accessory muscles of inspiration when the patient attempts to swallow liquids.44 Overwhelming terror accompanies the phenomenon and may generalize to the sight of water or having water touch the face. Aerophobia, an extreme fear of air in motion, can be elicited in some patients by blowing air across the face. This results in muscle spasms in the neck and pharyngeal regions.50,51 Signs of autonomic dysfunction, such as excessive salivation and priapism, may be noted. Hyperactive deep tendon reflexes with Babinski’s signs and nuchal rigidity often are present. Seizures and focal weakness are rare. Approximately 20% of cases manifest as paralytic or “dumb” rabies, with limb weakness and fever; consciousness initially is spared. Rabies may be very difficult to diagnose because of the lack of the typical irritability and hydrophobia, and may be confused with Guillain-Barré syndrome. It also may be difficult to make a distinction between the paralytic form of rabies and Guillain-Barré syndrome on the basis of clinical, pathologic, or electrophysiologic criteria. Features that may suggest paralytic rabies instead of Guillain-Barré include persistent fever from the onset of limb weakness; intact sensory function except at the bite site; bladder dysfunction; and percussion myodema (a mounding of the muscle at the percussion site that lasts a few seconds, most easily elicited on the chest, deltoid, and thigh).46 Neuropathologic findings of motor axon neuropathy in the absence of motor neuron degeneration and inflammation also may help with the recognition of paralytic rabies, although these findings are not unique to rabies.52 The two forms of classic rabies can overlap or progress from one to the other.

The nonclassic form of rabies is seen with rabies contracted from bats or from dogs in Thailand. This form is associated with more pronounced motor and sensory deficits than those typical for classic rabies of either form, brainstem signs such as cranial nerve abnormalities (dysarthria, dysphagia), choreiform movements, ataxia, nystagmus, and vertigo. Seizures are more common in this form, whereas phobic spasms are rare.

Eventually, in all forms of rabies, coma occurs, generally 7 to 10 days after onset of the acute neurologic phase. Hydrophobia persists, accompanied by prolonged apnea, and generalized flaccid paralysis. Seizures may ensue, and ultimately the disease culminates in respiratory and vascular collapse. Unless the patient is supported by intensive care, death ensues in 2 to 3 days.53

■ DIAGNOSIS AND MANAGEMENT

In most clinical situations, rabies is not considered until late in the course of the disease. Antemortem diagnosis may involve isolation of virus and detection of viral RNA, antigen, or antibody. Brain biopsy is the definitive method for isolating virus, but the risks associated with this procedure prohibit its use in most cases. Detection of antigen from the peripheral nerves of a nuchal skin biopsy specimen frequently has been successful and is superior to detection of antigen in corneal epithelium.

Cerebrospinal fluid (CSF) analysis will show a pleocytosis, and in some cases, virus can be isolated or viral antibody detected in the fluid. Saliva also may yield virus. Antibody to rabies virus is variably detected in serum and generally is not seen until the second week of illness. Results of direct fluorescent antibody testing for viral antigen in saliva, corneal impressions, and nuchal skin biopsy specimens are variably positive, and such tests should be repeated if the diagnosis remains in doubt. Rabies virus RNA is present in saliva, urine, and CSF, and detection in saliva and urine using reverse transcriptase–polymerase chain reaction (RT-PCR) amplification is a promising advance.33,34,55 Magnetic resonance imaging (MRI) of the brain may be useful in distinguishing rabies from other forms of encephalitis.36 Because evidence of infection may not be present for many days after the onset of illness, negative findings on antemortem studies do not rule out the disease. Also, antemortem diagnosis is important in limiting contacts with the victim and ascertaining that no others were exposed to the rabies source.

Once manifested clinically, rabies usually is fatal within 3 to 10 days; with intensive care unit (ICU) support, survival times are as long as 4 months, but the outcome remains dismal. No clearly effective rabies treatment currently exists; pooled human rabies immune globulin given intrathecally, cytarabine, adenine arabinoside, ribavirin, acyclovir, and interferon all have been administered after onset of symptoms, without success.5,6,7,36,49,57,58 In vitro, high concentrations of ketamine inhibit replication of rabies virus and have been shown experimentally to reduce brain infection. Corticosteroids have been shown to increase the mortality rate in mouse models.59 There is only one well-documented case of survival from rabies in a patient who had not received any postexposure prophylaxis (PEP).59 This 11-year-old girl from Minnesota was treated with ketamine for sedation, beta-blockade, antiseizure medications, and neuromuscular blockade. She was not given immune globulin or vaccine, to avoid stimulating an immune response. After 4 months in an ICU, she survived with intact sensorium but significant neurologic sequelae. Unfortunately, two other rabies victims who subsequently were treated with the same regimen did not survive.52 Only five other patients have been reported to have survived clinical rabies, with a satisfactory neurologic status in only one. All five had received some form of preexposure or postexposure prophylactic treatment, and none had rabies virus isolated or antigen detected, raising the question of whether the survivors in fact had the disease.52

■ POSTEXPOSURE PROPHYLAXIS ASSESSMENT

Despite the fact that human rabies is extremely rare in the United States, from 20,000 to 39,000 people a year receive PEP; direct costs of delivering prophylaxis are estimated at approximately $2500 per case, with an additional $1100 cost...
to the patient in the form of lost wages, child care, and transportation.\textsuperscript{60,61} From 30 to 60\% of treatments probably are avoidable because the exposure was in the low-risk category, no exposure occurred, or animals were not tested or observed appropriately.\textsuperscript{62-64} Accordingly, it is imperative that practitioners understand the regional risk of rabies, animal handling procedures, indications for prophylaxis, and recommended treatment measures. The clinical scenario should be discussed with public health officials to reduce unnecessary treatments. Local or state agencies should be contacted first because they are most familiar with the animals in the area. If immediate consultation is required and local agencies are unavailable, emergency physicians can call the CDC’s clinician information line, 877-554-4625, which is available 24 hours a day, 7 days a week.

The decision about whether to begin PEP after a bite depends on a number of factors: the type of exposure, the location of the incident, and availability of the biting animal (Table 129-1). Treatment decisions may be modified if the animal is available for testing or observation.

### Exposure

Bites are considered significant exposures; nonbite exposures that involve contamination of either a mucous membrane or an open wound (one that has bled within 24 hours) with saliva also may necessitate prophylaxis. Petting a rabid animal and contact with its blood, urine, or feces are not considered exposures.\textsuperscript{40} Skunk spray exposure does not require prophylaxis. Dry virus is not infectious.

### Biting Animal

In the United States, high-risk animals are raccoons, skunks, foxes, bats, and coyotes. Dogs found along the U.S.-Mexico border and in developing countries also are high-risk animals. Wild carnivores in areas in which rabies is endemic may be infected with rabies; the risk of transmission of rabies to humans from the bites of these animals is approximately 10 times lower than the risk from the predominant reservoir but high enough to warrant prophylaxis.\textsuperscript{65} Therefore, bites from most wildlife require immediate prophylaxis; exceptions, as noted later on, are lagomorphs and rodents. Significant nonbite exposures to these animals also constitute grounds for initiation of treatment. PEP for the victim may be discontinued if the animal is proved not to be rabid after testing.

Transmission of rabies from bats appears to have occurred from seemingly unimportant or unrecognized bites. Accordingly, the threshold for providing treatment after bat exposures is exceedingly low. The CDC recommends that “postexposure prophylaxis should be considered when direct contact between a human and a bat has occurred, unless the exposed person can be certain bite, scratch or mucous membrane exposure did not occur.”\textsuperscript{40} PEP is recommended when a bat is found indoors in the same room with a person who might be unaware that a bite or direct contact had occurred (such as someone sleeping, an unattended child, or a mentally disabled person) and raccoons cannot be ruled out by testing the bat. Prophylaxis would not be recommended for other household members unless contact with the bat had occurred.

Small rodents (squirrels, gophers, rats, chipmunks, and guinea pigs) and lagomorphs (rabbits and hares) are very unlikely to carry rabies and thus are low risk. However, in areas in which raccoon rabies is endemic, groundhogs (woodchucks) have been found to be rabid in significant numbers. Woodchucks accounted for 93\% of the 371 cases of raccoons reported to the CDC between 1990 and 1996 and for 43 of the 44 cases among rodents and lagomorphs in 2006.\textsuperscript{5} Current recommendations are to consult state or local health departments before initiation of PEP for cases involving rodents. Bites from rodents outside the United States should receive prophylaxis.

Bites from livestock should be considered individually, and public health officials should be consulted.\textsuperscript{40} No human cases of rabies from livestock have ever been reported in the United States.\textsuperscript{5}

Domestic animals, particularly urban cats and dogs, in the United States are generally at low risk, with the exception of dogs at the U.S.-Mexico border. However, domestic animals in endemic areas may be at somewhat higher risk. Healthy-appearing domestic animals (dogs, cats, and ferrets) should be observed for 10 days, and PEP for the victim should be withheld unless the animal becomes ill. In nonendemic areas, PEP usually is withheld even if the animal is not available. Rabies has rarely been diagnosed in vaccinated domestic animals and appears to have occurred only in animals that had received

*During the 10-day observation period, begin postexposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.
†The animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results for the animal are negative.

only one vaccination in their lifetime.21,66 Bites from dogs in developing countries should always be considered high risk, and prophylaxis should be given without waiting for test results.

**Biting Incident**

Animals that are behaving oddly, or that bite without provocation, have a higher risk of carrying rabies. However, the circumstances of the bite should be taken into consideration only in evaluating a bite from an otherwise low-risk animal, such as a dog or cat.

**Animal in Captivity**

Wild animals that have been caught should be sacrificed immediately and the head sent, under refrigeration, to an appropriate laboratory for rabies fluorescent antibody testing. Unless the risk of transmission is low, the victim should begin prophylaxis, which may be discontinued when the results of the test are known. Domestic animals (dogs, cats, ferrets) in the United States that are apparently healthy should be observed for 10 days; if the animal does not become ill, the victim does not require treatment. If the animal appears sick or is stray or unwanted, it should be sacrificed and treated immediately and the victim treated accordingly.

---

**POSTEXPOSURE PROPHYLAXIS**

Prophylaxis consists of three steps: wound care, passive immunization, and active immunization. No step in this treatment should be omitted. When prophylaxis appears to be indicated, treatment should be begun immediately. Discussion with local public health officials will decrease unnecessary treatment, and advice is available from either state health officials or the CDC 24 hours a day. It is not known whether, or for how long, it is safe to delay treatment, nor is such delay recommended.67 On the other hand, if prophylaxis is indicated, it should be administered regardless of the duration of the delay because evidence exists that the incubation period of rabies can be more than a year.

**Wound Care**

Although wound care should never be relied on as the only preventive measure, it is an essential part of postexposure rabies prevention, especially because in rare cases, rabies subsequently developed in persons who received what was thought to be appropriate immunoprophylaxis. Furthermore, wound treatment may be the only prevention available for a victim in the wild who is days or weeks away from medical care. Rabies virus is easily killed by sunlight, soap, or drying. Experimental studies have shown that the combination of scrubbing and flushing the wound with benzalkonium chloride, 20% soap solution, or Ivory soap was nearly 100% protective when performed within 3 hours of inoculation of virus.68 For wounds in which rabies transmission is of concern, the CDC recommends immediate and thorough washing with soap and water and also application of a virucidal agent such as povidone-iodine* (Box 129-1). Wounds should be scrubbed or swabbed, not simply flushed.69 After cleansing the wound as described above, rinse with water or saline.

**Immunoprophylaxis**

Rabies immunoprophylaxis requires both passive immunization with antibody (immune globulin) and active immunization with vaccine (Box 129-2). It is essential that both parts of this regimen be given, even when treatment is delayed. Human rabies immune globulin (HRIG), 20 IU/kg, should be administered as soon after the bite as possible, but not longer than 7 days after tissue culture vaccine has been given. If anatomically feasible, the entire dose of HRIG should be infiltrated into and around the wound(s); any remaining volume should be injected intramuscularly at a site distant from the vaccine.8

Human diploid cell vaccine (HDCV) is the vaccine most widely available in the United States. The first dose should be administered on the day of the bite; four subsequent injections are required. The vaccine should be administered in the deltoid rather than the gluteal region, to avoid accidental injection into fat, which will prevent antibody formation.55,70 HRIG and HDCV should be given in different anatomic sites and

---

**BOX 129-1**

**Rabies Wound Treatment**

- Early treatment is essential (less than 3 hours after the bite/injury occurred).
- Scrub the wound and its edges with soap and water.
- If the wound is a puncture, swab deeply in the wound and around its edges.
- Follow with application of a virucidal agent: 1% or 2% benzalkonium chloride or povidone-iodine*
- Rinse.

*Povidone-iodine has never been tested but is recommended by the Centers for Disease Control and Prevention. Tetanus prophylaxis should be given as indicated by patient’s current immunization status.

**BOX 129-2**

**Rabies Postexposure Immunoprophylaxis**

| Wound cleansing | All postexposure prophylaxis should begin with immediate thorough cleansing of all wounds with soap and water. If available, a virucidal agent such as povidone-iodine solution should be used to irrigate the wounds. |
| Nonimmunized Persons | Human rabies immune globulin (HRIG) | If possible, the full dose should be infiltrated around any wound(s), and any remaining volume should be administered IM at an anatomic site distant from vaccine administration. Also, HRIG should not be administered in the same syringe as for vaccine. Because HRIG may partially suppress active production of antibody, no more than the recommended dose should be given. |
| Vaccine | Human diploid cell vaccine (HDCV) or purified chick embryo culture vaccine (PCECV) 1.0 mL, IM (deltoid area), one each on days 0, 3, 7, 14, and 28. |
| Previously Immunized Persons | HRIG | HRIG should not be administered. |
| Vaccine | HDCV or PCECV 1.0 mL, IM (deltoid area), on days 0 and 3. |

never mixed in the same syringe. All known treatment failures since 1980 have occurred after a deviation from the recommended regimen. Patients either did not have their wounds cleansed with soap and water, did not receive rabies vaccine in the deltoid region, or did not receive HRIG at the wound site.

Local reactions (itching, erythema, pain, or swelling) occur in 30 to 74% of PEP recipients; systemic reactions including headache, myalgia, and nausea occur in 5 to 40% of recipients, usually those who receive frequent vaccine boosters.20 An immune complex type of reaction involving urticaria, arthralgia, arthritis, angioedema, nausea, and vomiting occurs in approximately 6% of patients who receive boosters of HDCV; it is uncommon in those receiving primary vaccination.20 Two alternative vaccines, rabies vaccine adsorbed (RVA) and purified chick embryo culture (PCEC) vaccine, also are available in the United States. Both appear to be associated with fewer hypersensitivity reactions in patients receiving boosters.74 Although HDCV may be administered intradermally for preexposure prophylaxis, neither RVA nor PCEC vaccine is approved for intradermal use.

Patients requiring rabies immunoprophylaxis when outside the United States may receive a different regimen and different vaccines from those used within the United States. Some countries still use vaccines derived from nerve tissue, rather than cell cultures, which are poorly immunogenic and carry a greater risk of side effects. In many areas, rabies immune globulin may not be available. The WHO has approved several treatment regimens that reduce cost by giving fewer vaccine injections, or using the intradermal route, which requires less medical personnel working with live rabies virus, veterinarians, and animal-control and wildlife personnel who have been trained in this technique.74-77 Additionally, the WHO recommends immune globulin only for severe bites.74 These regimens are not approved in the United States for PEP. The WHO cautions that intradermal injections should be administered only by medical personnel who have been trained in this technique.74-77 Additionally, because chloroquine has been shown to interfere with the antibody response to vaccine given intradermally, victims of bites who are currently receiving malaria prophylaxis (with any medication) should undergo postexposure rabies prophylaxis only by the intramuscular route.40,74 Accordingly, bite victims traveling abroad may require additional treatment when they return to the United States. Public health officials should be contacted for advice.

Prophylaxis, including both passive and active immunization, given during pregnancy does not result in an increase in fetal wastage, congenital defects, or side effects and should not be withheld when indicated.76 Corticosteroids, antimalarials, and other immunosuppressives can interfere with the development of active immunity and should be withheld during the course of treatment if possible. Patients who must receive these drugs, or those who are immunosuppressed, should receive prophylaxis by the intramuscular route and have antibody titers checked at 2 to 4 weeks after completion of the injection series.40,70 Patients with a history of hypersensitivity should nevertheless be cautiously given immunoprophylaxis in a controlled setting, with antihistamines and epinephrine available.40 Rabies has been reported in a patient who was sensitive to equine antirabies immune globulin and was not given passive immunization.50,77

### PREEXPOSURE PROPHYLAXIS

For people with frequent exposures to rabies, preexposure prophylaxis may be indicated.40 Such persons include laboratory personnel working with live rabies virus, veterinarians, animal handlers, and those spending long periods in countries in which rabies is endemic and medical care is difficult to obtain (Table 129-2). Preexposure prophylaxis guarantees protection for persons who incur continuous and unapparent exposures (e.g., lab workers); it also allows protection when postexposure therapy may be delayed (e.g., in remote areas). After an exposure, patients who have had preexposure

prophylaxis do not require HRIG; vaccine is given only on days 0 and 3 (see Box 129-2). However, travelers should be aware that chloroquine prophylaxis for malaria can interfere with antibody response to preexposure vaccination given intradermally; therefore, the vaccination regimen should be completed at least 1 month before initiation of malaria prophylaxis, or the preexposure regimen should be given intramuscularly.7,40

**KEY CONCEPTS**

- The epidemiology of rabies in the United States has undergone a major evolution, with the primary source of this disease now in wild animals rather than in domestic animals.
- Despite an increase in the numbers of terrestrial wild animals with rabies, particularly raccoons, the predominant threat to humans in the United States appears to be contact with bats.
- PEP is indicated for victims of bites or significant nonbite exposures from wild carnivores in endemic areas and bat contact when a bite cannot be ruled out and the bat cannot be tested. In most cases in the United States, healthy domestic animals should be observed before initiation of PEP.
- Discussion with public health officials is highly recommended to guide decisions about PEP and reduce the number of unnecessary treatments.
- PEP involves three important components: local wound care with soap and water and a virucidal agent, passive immunization with rabies immune globulin, and active immunization with vaccine. The regimen should be adhered to precisely because treatment failures have occurred when it was not followed.

Chapter 130  AIDS and HIV Infection

Richard E. Rothman, Catherine A. Marco, and Samuel Yang

Perspective

History

The first cases of AIDS came to light in 1981, when reports of Kaposi’s sarcoma (KS) and Pneumocystis pneumonia (PCP) in previously healthy homosexual men appeared in the literature. Shortly thereafter, it was recognized that these patients shared the common characteristic of a defect in cell-mediated immunity; accordingly, the clinical disease was designated the acquired immunodeficiency syndrome (AIDS). In 1983, a ribonucleic acid (RNA)–type retrovirus, the human immunodeficiency virus (HIV), was identified as the causative agent for the syndrome. The development of an antibody assay in 1985 permitted serologic diagnosis, allowing researchers to track the HIV epidemic and identify the principal modes of and risk factors for disease transmission. Significant therapeutic advances have occurred over the past 2 decades with institution of prophylaxis for opportunistic infections and introduction of highly active antiretroviral therapy (HAART) for slowing progression of disease. Despite these advances, HIV continues to be a major public health threat and is responsible for a large number of emergency department (ED) visits, for both acute and subacute conditions, each year.

Epidemiology

Most epidemiologic data regarding HIV infection are derived from studies in patients with illness that meets the definition of AIDS. The most up-to-date definition of AIDS, published in 1997 by the Centers for Disease Control and Prevention (CDC), is shown in Box 130-1.

Case definitions include either the presence of one or more AIDS-indicator conditions or laboratory evidence of severe immunosuppression as evidenced by a CD4+ T lymphocyte count of less than 200 cells/µL.

Worldwide estimates indicate that approximately 39.5 million adults and 2.3 million children were living with HIV/AIDS at the end of 2006. Cumulative HIV-related deaths totaled 25 million. Approximately 95% of HIV-infected persons live in the developing world. Sub-Saharan Africa has the highest levels of infection, with more than 25 million persons living with disease and more than 3 million newly reported cases in 2003 (representing approximately 60% of all incident cases). The medical and economic impacts of HIV and AIDS continue to devastate these areas, because these populations have the least access to the medical, social, and economic resources that might prevent new disease or delay the progression of HIV-related illnesses.

In developed countries significant progress has been made in controlling the HIV epidemic. In 1996, for the first time since HIV was recognized, there was a decline in the incidence of AIDS and the number of AIDS-related deaths, attributed primarily to availability of new antiretroviral therapies. Unfortunately, the rates of decline in AIDS cases and AIDS deaths have slowed over the past several years. In the United States an estimated 56,000 new cases of HIV were reported in 2007 and an estimated 1 million persons were living with HIV or AIDS.

Within the United States, HIV-positive persons are concentrated primarily in large urban settings. Until 1987, New York City, Newark, Miami, San Francisco, and Los Angeles accounted for nearly 50% of AIDS cases. Although these cities still represent high-intensity pockets of infection, significant increases also have been seen in smaller metropolitan areas. The percentage distribution of AIDS cases by area of residence in 2001 was 81% from large metropolitan areas and 7% from nonmetropolitan areas. As of 2007 the ten states reporting the highest number of cumulative AIDS cases were New York, California, Florida, Texas, New Jersey, Pennsylvania, Illinois, Maryland, Georgia, and Massachusetts.

The incidence of HIV infection has remained relatively stable, at 40,000 new cases per year, although new methods of estimating HIV incidence currently under investigation suggest that this may be an underestimate. Approximately 80% of AIDS cases have occurred in adult men, 18% in adult women, and just over 1% in children. The proportion of adult women among those infected with HIV has increased over the past several years, with adult women now representing 26% of those living with HIV/AIDS. Nearly one half of all people who are infected with HIV in the United States become infected before they turn 30, and the vast majority will die before reaching the age of 45 years. There is a disproportionate rate of infection among minority groups, with African Americans and Hispanics accounting for an ever-increasing proportion of new HIV cases and persons living with AIDS. In 2005, more than 70% of all AIDS cases diagnosed occurred in minority racial or ethnic groups.

The primary risk factors associated with an increased likelihood of acquiring HIV infection include homosexual or bisexual orientation, intravenous drug use, heterosexual exposure to a partner at risk, blood transfusion before 1985, and vertical and horizontal maternal-neonatal transmission. A greater

Salmonella septicemia, recurrent
Toxoplasmosis of brain, onset at age >1 month

number of risk factors is associated with a greater likelihood of infection. CDC HIV surveillance data demonstrate significant changes in the distribution of newly acquired HIV cases over the past several years. A relative decrease in newly acquired HIV infection has been documented among homosexual and bisexual men, and a relative increase in incidence of infection has been noted among intravenous drug users and heterosexual contacts. The change in the distribution of AIDS cases in adults and adolescents by mechanism of transmission since the start of the HIV epidemic is shown in Figure 130-1.

During the past several years, the greatest percentage increase in reported AIDS cases has occurred among women (attributed principally to heterosexual exposure from an infected partner), in minority populations, and among children. Because these populations often lack access to primary health services and frequently are underinsured, an emerging trend has been toward increasing use of ED services by patients with HIV infection and AIDS. Surveillance data from centers in Baltimore, Chicago, Atlanta, and New York City indicate HIV seroprevalence rates ranging from 2 to 15%.5

HIV is a cytopathic human retrovirus that belongs to the lentivirus subfamily. The two major subtypes of HIV are HIV-1 and HIV-2. HIV-1 is the predominant subtype worldwide and is the cause of AIDS. HIV-2 causes a similar immune syndrome but is rarely seen in the United States being restricted primarily to western Africa.

The HIV virion is composed of a central single-stranded RNA molecule and the enzyme reverse transcriptase. These are surrounded by a core protein and a lipid bilayer envelope that contain virally encoded transmembrane proteins critical for recognition and attachment to target host lymphocytes (predominantly CD4+ cells). HIV-1 has been isolated from a variety of body fluids including blood, serum, semen, vaginal secretions, urine, cerebrospinal fluid (CSF), tears, breast milk, bone marrow, alveolar fluid, synovial fluid, amniotic fluid, and saliva. Only a few modes of transmission have been proved: in semen, vaginal secretions, blood or blood products, and breast milk and transplacental transmission in utero. There have been no instances of transmission by casual contact, although one case report described possible salivary transmission. The HIV virion is extremely labile and easily neutralized by heat and common disinfecting agents such as 50% ethanol, 35% isopropyl alcohol, 0.3% hydrogen peroxide, disinfectant (Lysol), or a 1:10 solution of household bleach (sodium hypochlorite).

HIV selectively attacks cells within the immune system (primarily T4 helper cells, but macrophages and monocytes also may be involved), a characteristic that accounts for much of the immunodeficiency it produces in affected persons. HIV-1 transmembrane proteins gp41 and gp120 play a critical role in recognition and attachment of HIV virions to receptors on host lymphocytes. After infection, viral RNA is reverse-transcribed into deoxyribonucleic acid (DNA) by reverse transcriptase, one of the critical enzymes required for HIV replication. The viral genome thus becomes permanently integrated into the host’s genome. Once integrated, retroviral DNA may lie dormant, or it may be actively transcribed and translated to produce virally encoded proteins and new HIV virions. HIV protease is another critical retroviral enzyme in the life cycle of the virus, responsible for activation of viral protein precursors into the functional enzymes required for virion infectivity.
Primary HIV exposure is characterized by a transient viremia and a decrease in CD4⁺ cell counts, followed by establishment of equilibrium between virus and host immunity. A persistent latent period, during which the virus lies dormant in the host genome, can last for years. The “set point” or steady-state viral load level in the blood of the patient allows prediction of long-term clinical outcomes. Lower levels of viremia correlate with longer clinical latency periods. In the later stages of HIV infection, a sudden increase of viremia correlates with a dramatic decrease in CD4⁺ T lymphocytes. These hematologic changes are followed by the appearance of opportunistic infections or malignancies and ultimately death.

HIV-1 is highly heterogeneous. Multiple genetic subtypes exist in a variety of geographic and sociologic settings. Further genetic diversity exists within individual hosts owing to the highly mutable character of the virus. High error rates, which are associated with reverse transcription, ensure extensive viral diversity, a critical factor in the pathogenesis of infection and ongoing emergence of drug-resistant phenotypes.  

### Tests for Human Immunodeficiency Virus Infection

#### General Approach

HIV infection most commonly is established by HIV serologic studies or by detection of antibodies to the virus. Testing involves sequential use of an enzyme immunoassay (EIA) and a Western blot assay. Criteria for positive results are positive results on EIA followed by Western blot assay. EIA detects the binding of specific serum antibodies to HIV antigens that are adherent to a microtiter plate. Western blot assay detects electrophoretically separated viral antigens in the patient’s serum. A positive Western blot result requires detection of two of the following: p24, gp41, or gp120/160. Final HIV serology results are reported as positive, negative, or indeterminate. Overall sensitivity and specificity rates for HIV serologic testing are greater than 99.9%.

False-negative HIV test results are accounted for primarily by testing too early, during the “window period” (usually the first several months) of acute infection, after viral transmission but before the appearance of antibodies. Rates of false-negative testing range from 0.3% in high-prevalence populations to less than 0.001% in low-prevalence populations. Ninety-five percent of false-negative test results become positive by 3 months and 98% by 6 months. A less common explanation for false-negative results is seroreversion, which may occur in late-stage disease or in patients who are aware of their HIV serostatus.

Advantages of rapid test technologies include ease of specimen collection, reduced costs, rapid availability of results, and improved compliance with testing.

#### Human Immunodeficiency Virus Testing in the Emergency Department

Traditionally it has been thought that serologic testing of patients for HIV infection in the ED is not indicated. With the advent of rapid testing methodologies, the concept of ED testing for HIV infection is being reexamined. This is being driven by a number of factors, including the ease of the testing process, the recognized value of knowing a patient’s HIV status if the acute clinical presentation raises suspicion for disease, and the now-widespread recognition that early detection of HIV infection (and early therapeutic intervention) provides a significant health benefit both for individual patients and for the community. Benefits to the infected patient include delaying progression of disease and reducing the risk of opportunistic infections; an important advantage for the community includes decreased disease transmission associated with reduction in high-risk behavior in persons who are aware of their HIV serostatus.

The most recent CDC guidelines for HIV testing, released in 2007, recommend that such testing be performed in health care settings. These guidelines give special emphasis to the
role of the ED, driven largely by multiple studies showing that the ED is the most frequent site of encounter with the health care system for persons with unrecognized HIV infection (representing approximately 30% of all patients infected). Shortly after the CDC guidelines were published, the American College of Emergency Physicians (ACEP) released a corresponding policy statement supporting the availability of HIV testing for evaluation of related acute care conditions, indicating that testing and results should be available in an expeditious and efficient fashion, as with the management of other conditions. With regard to HIV screening, the policy suggests that individual institutions need to consider the appropriateness and feasibility of screening based on the particular characteristics of their ED and available resources. A list of important considerations that must be attended to before initiation of such a program is provided in the ACEP statement. For institutions considering establishing ED-based HIV testing and screening programs, the American Hospital Association provides an online guide.

A number of EDs around the country have implemented HIV testing using both rapid and traditional testing approaches. Such HIV testing programs have included both routine, broad-based screening and focused testing based on clinical suspicion. Funding for implementation has been supported in part by the CDC as well as by state and local health departments. In spite of some success, barriers to implementing screening (more so than clinically based testing) remain. Most important among these barriers are time constraints, financial burdens, impact of testing on ED crowding, and concerns regarding the responsibility for ensuring follow-up care.

Emergency physicians need to be aware of state laws and local regulations governing testing. Although separate informed consent or formal pretest counseling is no longer considered mandatory by the CDC, many states have laws requiring informed consent before testing. AIDS is a reportable disease in all 50 states, and HIV infection is reportable in most states. As of 2007, 47 states are conducting confidential name-based HIV infection reporting, based on the 2005 CDC recommendations.

### CLINICAL FEATURES

The broad spectrum of disease presentation for HIV-related disorders ranges widely from asymptomatic seropositive status to severe, life-threatening complications of AIDS. Included are a wide variety of opportunistic infections, malignancies, and other HIV-related diseases. Nearly every organ system may be affected by HIV infection and related conditions. Because the differential diagnosis is so broad in scope for many ED presentations, this chapter addresses clinical symptoms, signs, and focused information on some of the more common disorders.

#### Initial Evaluation of the Human Immunodeficiency Virus–Infected Patient

The initial evaluation and management of the HIV-infected patient consist of rapid and early assessment of stability. Any problems with airway, breathing, and circulation must be promptly identified and appropriate interventions performed. For unstable patients, intravenous access, cardiac monitoring, and administration of oxygen typically are indicated. After initial stabilization, the remainder of the history and physical examination may be conducted.

Relevant elements of the history include information pertinent to the chief complaint, including duration, location, qualities, characteristics, level of distress, and relieving or inciting factors. The past medical history should identify a previous history of similar problems, the time of diagnosis of HIV infection, previous AIDS-defining conditions, recent hospitalizations, past surgical history, current medications, and allergies. The existence of an advance directive may be important historical information, because many HIV-infected patients have expressed opinions about the level of intervention desired in various clinical settings, particularly in critical care settings and at the end of life.

Information regarding potential risk factors for HIV infection may be appropriate to gather in the ED evaluation in patients not known to be HIV-seropositive, particularly in endemic areas. The infection rate may be surprisingly high, even for those patients with presenting complaints not associated with HIV infection. Furthermore, inquiries about risk factors help direct the medical evaluation, remind ED personnel of the potential for occupational exposure to the virus, and afford the opportunity to offer referral for testing and counseling to persons who engage in high-risk behavior. Many cases of early HIV infection may not be detected during ED evaluation because of a low clinical suspicion for the disease, particularly in areas with a low prevalence of AIDS. Although inquiries regarding risk factors may be offensive to some patients, any difficulty usually can be averted by beginning with tactful inquiries about previous HIV testing or risk factors and indicating that these questions are routinely asked in the ED.

After initial stabilization and gathering of historical information, a focused physical examination should be conducted. In elements of the examination relevant to the chief complaint, special attention should be paid to the identification of potentially treatable disorders.

The universal goals of ED management are to rapidly and effectively assess the patient, identify potentially life-threatening disorders, administer urgent interventions, generate an appropriate differential diagnosis, and provide or arrange for appropriate initial therapy, consultation, and disposition.

### Stages of Human Immunodeficiency Virus Infection

Several methods of classification and staging of HIV infection have been developed. The Walter Reed classification system is based on clinical and immunologic features. Other classifications are based on CD4+ counts. In 1993, the CDC case definition of AIDS incorporated CD4+ counts of less than 200 cells/µL as an AIDS-defining condition. The median survival time for untreated patients with AIDS is 3.7 years for those with CD4+ cell counts less than 200 cells/µL and 1.3 years for those with their first AIDS-defining complication (see Box 130-1).

### Primary Human Immunodeficiency Virus Infection

Acute HIV syndrome (acute seroconversion syndrome) commonly follows primary exposure by 2 to 4 weeks and may be associated with nonspecific flulike symptoms and signs such as fever, adenopathy, fatigue, pharyngitis, diarrhea, weight loss, and rash. Additional signs and symptoms such as myopathy, peripheral neuropathy, or other neurologic or immunologic manifestations are less common. These relatively nonspecific problems are seen in approximately 40 to 90% of patients and usually last 1 to 3 weeks. The differential diagnosis of acute HIV infection is broad in scope; considerations mainly include a wide variety of viral illnesses, such as Epstein-Barr virus (EBV) infection and viral hepatitis. Pres-
ence of a rash or mucocutaneous ulcers should raise suspicion for acute HIV seroconversion.

During the acute phase of HIV infection, results of standard HIV testing (enzyme-linked immunosorbent assay [ELISA] antibody testing) usually are negative, because the median time for seroconversion is approximately 2 months. If acute HIV infection is strongly suspected (on the basis of presentation and history of recent exposure), RNA viral load testing can be performed, either in the ED or by referral. Identification of acute HIV is important because HIV viral load is significantly higher during this phase of the illness and the risk of transmission is elevated. No current consensus has emerged among HIV experts, however, regarding the optimal timing and treatment regimen for acute HIV infection. Accordingly, any patient identified as having acute infection should be referred for urgent evaluation by an HIV specialist.

Predictors of Disease Progression

Although the rate of disease progression from initial HIV infection to development of AIDS-defining illnesses varies widely, the average time is 10 to 12 years. Some long-term nonprogressors have remained free of AIDS-defining conditions for more than 20 years. Clinical predictors of more rapid development of clinically significant immunodeficiency include oral candidiasis, oral hairy leukoplakia, dermatomal varicella, lymphadenopathy, and constitutional symptoms.20,21

The best predictor of immunologic susceptibility to opportunistic infection is the CD4+ cell count.22 Other laboratory markers of disease progression include neutropenia and plasma HIV-1 RNA determinations.

Complications

Systemic Symptoms and Signs of Human Immunodeficiency Virus Infection

Systemic symptoms and signs such as fever, weight loss, and malaise are common among patients presenting to the ED. The differential diagnosis is lengthy and includes a variety of infectious causes, malignancy, and drug reactions (Box 130-2). Fever is a common presenting complaint in patients with AIDS. Evidence of an infectious cause or other reason for fever should be sought by careful history and physical examination. Initial workup for the cause of fever in an immunocompromised patient may include a complete blood count, electrolytes, comprehensive metabolic panel (CMP), chest radiograph, urinalysis and culture, and blood cultures (aerobic, anaerobic, mycobacterial, and fungal). Additional testing, based on current and past medical history and physical exam, may include stool (for culture, examination for ova and parasites, and Gram’s stain), urine (for histoplasmosis and fungal and mycobacterial culture), and induced sputum (for smear fungal and mycobacterial culture) studies; erythrocyte sedimentation rate determination; liver function tests; serum cryptococcal antigen assay; and serologic tests for syphilis, Toxoplasma, and Cryptococcus. In the absence of neurologic signs or symptoms or if no other source of fever is identified, lumbar puncture should be considered after a cranial computed tomography (CT) scan. Two of the most common causes of febrile illness in patients with later-stage HIV are disseminated atypical mycobacterial infections and cytomegalovirus (CMV) infection.

Atypical mycobacterial infections, caused by Mycobacterium avium complex or M. kansasii, cause disseminated disease in up to 50% of patients with AIDS and usually are associated with CD4+ counts less than 100 cells/μL. Presentation typically includes severe weight loss, diarrhea, and various constitutional symptoms, such as fever, malaise, and anorexia. Anemia is common. Ziehl-Neelsen (acid-fast) stain of stool or other body fluids commonly yields positive findings, and the organism also can be cultured from blood. Treatment for M. avium complex infection consists of clarithromycin, 500 mg twice a day, and ethambutol, 15 mg/kg daily. Such regimens often reduce the degree of bacteremia and symptomatology but typically do not eradicate the organism. Clarithromycin or azithromycin should be used for prophylaxis in patients with CD4+ counts below 50 cells/μL.

Disseminated CMV infections typically occur in patients with CD4+ counts below 50 cells/μL. In addition to fever, patients often present with odonophagia, abdominal pain, and diarrhea secondary to esophagitis and colitis. Diagnosis usually requires endoscopy or colonoscopy for biopsy, because culture has poor sensitivity. Complications include gastrointestinal bleeding and perforation. Treatment includes immune restoration with antiretrovirals and a regimen of ganciclovir or foscarnet. Oral ganciclovir is used for prophylaxis in patients with CD4+ counts below 50 cells/μL.

Some patients with HIV infection and fever or other systemic symptoms may be managed on an outpatient basis if they are not severely immunosuppressed and not systemically ill. Requirements for discharge from the ED include ability to take oral fluids, assurance of timely follow-up including obtaining results of ED-initiated cultures, and capability of providing adequate self-care. Indications for hospital admission include
toxic appearance, neutropenia with fever, active bleeding, or other need for urgent diagnosis and treatment. For patients with persistent fevers, in whom one or more of the discharge criteria are not met, hospitalization is warranted.

**Pulmonary Involvement**

Pulmonary manifestations of HIV infection are among the most common reasons for ED visits among patients with AIDS. Careful consideration is mandated to establish the diagnosis and initiate early treatment. The differential diagnosis of respiratory involvement is broad in scope; considerations include bacterial infections (e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Chlamydia pneumoniae*, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Mycobacterium tuberculosis* [MTB], *Mycobacterium avium-intracellulare* [MAI] complex), fungal infections (e.g., *Pneumocystis jiroveci* [formerly *Pneumocystis carinii*], *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Aspergillus fumigatus*, * Blastomyces dermatitides*), viral infections (e.g., cytomegalovirus, adenoviruses), protozoal infections (e.g., *Toxoplasma gondii*), malignancies (e.g., Kaposi’s sarcoma, carcinoma, lymphoma), and others (e.g., lymphocytic interstitial pneumonitis, pulmonary hypertension, pulmonary embolism).

Occurrence of specific pulmonary infections often is related to CD4+ counts. In patients with pulmonary involvement and CD4+ counts greater than 500 cells/µL, encapsulated bacteria, tuberculosis, and malignancies are common. With lower CD4+ counts, PCP, infections due to atypical mycobacteria, fungal infections, cytomegalovirus infection, lymphoma, lymphoproliferative disorders, and Kaposi’s sarcoma are seen with increasing frequency.

Patients with fever and a productive cough are likely to have a bacterial pneumonia, whereas a nonproductive cough is more likely to accompany PCP, other fungal infections, or neoplasm. Hemoptysis often is associated with pneumococcal pneumonia and tuberculosis. Fulminant respiratory failure is most likely to be caused by *Pneumocystis jiroveci* (the agent of PCP) or CMV.

Diagnostic evaluation of patients with HIV infection and suspected pneumonia should routinely include pulse oximetry, chest radiography, and complete blood count. Additional testing based on the stage of disease and clinical presentation may include arterial blood gas (ABG) analysis, serum lactate dehydrogenase determination, assays for serum cryptococcal antigen and urine *Histoplasma* antigen, and induced sputum specimen studies including Gram stain, acid-fast bacillus (AFB) smear, and Gomori, Giemsa, or immunofluorescent antibody (IFA) staining for *Pneumocystis jiroveci*. Blood culture specimens should be obtained in the ED from all HIV-infected patients with suspected pneumonia; this component of the evaluation becomes increasingly important in patients with later-stage disease. Blood culture collection, however, should not delay the initiation of antimicrobial therapy.

Although radiographic findings in many pulmonary complications may be nondiagnostic, certain patterns may be suggestive of specific disorders. A focal infiltrate on the plain chest film often suggests bacterial pneumonia, whereas a diffuse interstitial or perihilar, granular pattern is associated with PCP. PCP is suggested by increased serum lactate dehydrogenase and hypoxia (especially exercise-induced), which may be more severe than expected from radiographic findings. Hilar adenopathy with diffuse pulmonary infiltrates suggests cryptococcosis, histoplasmosis, mycobacterial infection, or neoplasm. Kaposi’s sarcoma (KS) can manifest with cough, fever, and dyspnea and may mimic PCP on the chest radiograph. Table 130-1 lists common radiographic findings and associated conditions in the HIV-infected patient.

As with all disease processes, ED management of pulmonary complications must first include stabilization with appropriate support of airway, breathing, and circulation. Definitive airway management may be indicated in severe cases. Volume repletion or pressors, or both, may be indicated for hypotension. Other treatment measures should include administration of supplemental oxygen and volume repletion if indicated. If the diagnosis can be ascertained or is strongly suspected, specific treatment should be instituted while the patient is in the ED, particularly if PCP is suspected. If the symptoms are of new onset or there has been a change from previous status, hospitalization should be considered. Decisions regarding patients with known pulmonary involvement are based on comparison with baseline status, the effectiveness of ongoing or previous treatment, and the individual’s ability to obtain outpatient follow-up observation (see “Disposition”). The Pneumonia Outcomes Research Team (PORT) study did not include HIV-infected patients, and most experts suggest that hospital admission should be more readily considered for patients with HIV infection and pneumonia. Staging systems for predicting death from HIV-associated pneumonia found that clinical factors associated with increased mortality include the presence of neurologic symptoms, respiratory rate of 25 breaths per minute or less, and creatinine level greater than 1.2 mg/dL.22

Bacterial infections are the most frequent type of pulmonary infection among patients with AIDS and commonly are caused...
by *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and numerous other organisms. Infections with *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Legionella* are relatively less common. *P. aeruginosa* is a more common pathogen in later stages of AIDS. Presentations of bacterial pneumonia may be typical or atypical in symptoms, duration, and severity. Severely ill patients with pneumonia being managed in an ICU should be treated with linezolid or vancomycin, an antipseudomonal agent, in addition to a macrolide or respiratory fluoroquinolone.

### Pneumocystis Pneumonia

PCP is one of the most common opportunistic infections in AIDS. More than 80% of patients with AIDS acquire PCP at some time during their illness, and it is the initial opportunistic infection in many cases. As noted earlier, PCP is caused by the organism *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*—the original basis for the “PC” in PCP, which remains in use to refer to *Pneumocystis pneumonia*). Although *P. jiroveci* traditionally is classified as a protozoan, its morphology has been suggested to closely resemble that of a fungus. The incidence of PCP has declined since the widespread use of HAART.

Patients typically present with an insidious cough (often nonproductive), dyspnea, unexplained fever for longer than 2 weeks, chest pain, and fatigue. The chest radiograph commonly shows a diffuse interstitial infiltrate but also may be normal in appearance or reveals asymmetry, nodules, cavitation, or bullae. Considerations in the differential diagnosis include viral, bacterial, mycobacterial, fungal, and protozoal pneumonias, as well as malignancies. The more common causes to be considered in the differential diagnosis are shown in Box 130-2. Negative findings on the chest radiograph are reported in up to 20% of patients ultimately found to have PCP. In situations in which a high clinical suspicion exists for PCP, chest CT should be performed; CT findings frequently are suggestive of PCP. Gallium scanning of the chest also offers improved sensitivity over that of chest radiography, but this modality generally is not available in the ED and is associated with a high false-positive rate. Serum LDH often is elevated in patients with PCP (sensitivity of approximately 90%) but, again, has poor specificity so it cannot be used for definitive diagnosis.

In the ED, a presumptive diagnosis of PCP can be made in a patient with later-stage HIV (CD4+ count less than or in the range of 200 cells/μL) with unexplained hypoxia when other causes (e.g., pulmonary embolism) have been eliminated. The organism cannot be grown in the laboratory, so diagnosis relies on indirect IFA staining using monoclonal antibodies. Studies using induced sputum (often not practical to obtain in the ED) have a relatively low sensitivity. Accordingly, bronchoscopy (bronchoalveolar lavage, brush biopsy, or transbronchial biopsy) often is required for establishing the diagnosis. Establishment of a definitive diagnosis is not necessary before the initiation of treatment. Treatment should begin as early as possible with 15 to 20 mg/kg per day of trimethoprim and 75 mg/kg per day of sulfamethoxazole (TMP-SMX), given either orally or intravenously in two or three daily divided doses for a total of 21 days (e.g., two Bactrim DS tablets every 8 hours). Indications for intravenous therapy include tenuous respiratory status, an alveolar-arterial gradient above 45 mm Hg, and PaO2 below 60 mm Hg. Other therapeutic agents that can be used with PCP include pentamidine isethionate, dapsone, clindamycin plus primaquine, atovaquone, and trimetrexate. Steroid treatment (prednisone 40 mg PO, twice daily for five days with a 3-week taper) is recommended for patients with a PaO2 less than 70 mm Hg, or an alveolar-arterial gradient greater than 35 mm Hg. Most patients (60 to 80%) respond to therapy, although *Pneumocystis* persists in the lungs of two thirds of patients. All patients requiring steroids should be hospitalized because clinical status in those with PCP typically will worsen a few days after the initiation of therapy.

Adverse effects of TMP-SMX occur in up to 65% of patients with AIDS and are 20 times more common than in the general population (Table 130-2); such effects generally become apparent after 7 to 14 days of therapy. The most common adverse effects are nausea, vomiting, rash, fever, neutropenia, thrombocytopenia, hyponatremia, and hepatitis. Pentamidine can cause nausea, vomiting, diarrhea, neutropenia, hypoglycemia, hyperglycemia, renal impairment, hepatic toxicity, and orthostatic hypotension. Because sterile abscesses may develop at the injection site, intravenous infusion is preferred. Prophylaxis (with Bactrim DS, one tablet by mouth once daily) against PCP may be an important step in preventing reinfec-
tion and is recommended for patients with CD4+ cell counts below 200 cells/μL.

The mortality rate for PCP-associated respiratory failure is close to 60%. Patients requiring ventilatory support should be maintained on low tidal volumes and plateau pressures, because PCP is associated with an increased risk of pneumothorax. The presence of a pneumothorax in a patient with a low CD4+ count should be presumed to be caused by PCP, although KS, intravenous drug use, toxoplasmosis, and viral, fungal, and mycobacterial infections also can cause pneumothoraces. Asymptomatic patients with a small pneumothorax (involving less than 20% of lung volume) may be treated with observation or insertion of a Heimlich valve.

### Mycobacterium Tuberculosis Infection

The incidence of MTB infection in HIV-infected patients has increased dramatically, and it is estimated that over 10 million patients worldwide are co-infected with HIV and tuberculosis. HIV-infected patients have an estimated 50- to 200-fold increased risk of acquiring tuberculosis over the general population. The increase in tuberculosis among the HIV-infected population is thought to be due to a number of factors, including increased risk of reactivation of latent infection, high rates of infection after exposure, overlap in at-risk groups, and rapid progression to clinically significant disease. Tuberculosis may be a very early manifestation of AIDS.

Common presenting signs and symptoms include fever, cough, and hemoptysis, but in patients with immunosuppression, clinical manifestations are more atypical and extrapulmonary findings more common. Classic radiographic abnormalities are upper lobe alveolar lesions with cavitation accompanied by pleural effusions and mediastinal adenopathy. Findings may vary considerably, however, and atypical features and absence of radiographic abnormalities are more common among patients with lower CD4+ cell counts. Central nervous system (CNS), bone, visceral, skin, pericardial, eye, pharynx, and lymph node involvement also may occur.

The diagnosis of tuberculosis is based on a number of factors, including risk of infection, clinical presentation, direct examination of patient specimens, and identification of mycobacteria from cultures. Because a definitive diagnosis cannot be made in the ED, and the disease is transmitted by the aerosol route, isolation and hospital admission are indicated for any patient with suggestive clinical factors. Definitive laboratory diagnosis can be made by a nucleic acid amplification test (NAAT), an AFB smear, or culture evaluation of induced sputum specimens or samples obtained on bronchoscopy. NAAT has a higher sensitivity than AFB smear, and bronchoscopy or tissue biopsy a higher yield than induced sputum.

</table>

*This table represents only a partial list of adverse drug reactions. An authoritative source should be consulted whenever adverse drug reactions are suspected.

Purified protein derivative (PPD) skin testing generally is not helpful, particularly in patients with more advanced immunosuppression, because negative PPD test results are common among those infected. Dissemination of pulmonary infection results in miliary tuberculosis, which can affect nearly every organ system.

Treatment of patients with suspected tuberculosis should be determined in conjunction with an infectious disease specialist, taking into consideration local resistance as well as individual susceptibility tests. Patients with AIDS found to have tuberculosis should receive a four-drug regimen consisting of isoniazid, rifampin, pyrazinamide, and ethambutol, for 6 months. Second-line agents include ciprofloxacin, ofloxacin, kanamycin, amikacin, capreomycin, ethionamide, cycloserine, and para-aminosalicylic acid (PAS). Multidrug-resistant tuberculosis strains, resistant to multiple pharmacologic agents including isoniazid and rifampin, remain a concern. Empirical treatment for tuberculosis should be provided for HIV-infected persons with close contact with a patient with active tuberculosis. All HIV-infected patients with a positive result on PPD testing should receive tuberculosis prophylaxis with a regimen of isoniazid plus pyridoxine or rifampin plus pyrazinamide. Steps toward prevention of tuberculosis and its spread include the use of HAART, early identification of tuberculosis, early initiation of multidrug therapy, the use of respiratory isolation, and the use of personal respiratory protection devices.

Other Pulmonary Complications

Fungal pulmonary infections other than PCP may be seen in patients with AIDS. Such infections may include cryptococcosis, histoplasmosis, coccidioidomycosis, aspergillosis, nocardiosis, and blastomycosis. Cryptococcus neoformans is the most common fungal pathogen in patients with AIDS after Pneumocystis jiroveci, typically causing infection in patients with CD4+ counts less than 100 cells/µL. Radiographic findings often are nonspecific and may include consolidation, reticulonodular infiltrates, and nodules. Diagnosis is with serum cryptococcal antigen assay. Geographic regions with identified predilections for infection with specific pathogens include the eastern and central United States for Histoplasma, the south central and central United States for Blastomyces, and the southwestern United States for Coccidioides. Each of these pathogens is seen more commonly in late-stage HIV disease. In patients with cavitary lesions on chest radiographs, aspergillosis as well as tuberculosis and methicillin-resistant Staphylococcus aureus infection should be suspected.

Viral respiratory infections are common among HIV-infected patients. CMV infection is the most frequent, typically occurring with advanced immunosuppression. Radiographic findings may include alveolar consolidation or ground-glass opacities. Pulmonary malignancies include Kaposi’s sarcoma, non-Hodgkin’s lymphoma, Hodgkin’s disease, and bronchogenic carcinoma. Kaposi’s sarcoma typically is associated with hilar
peribronchovascular thickening, lower lobe reticulonodular opacities, adenopathy, pleural effusion, or focal consolidation. Pulmonary Kaposi’s sarcoma is treated with cytotoxic agents and HAART. Lymphoproliferative disorders also may have a pulmonary presentation among HIV-infected patients. Such disorders include lymphocytic interstitial pneumonia, nonspecific interstitial pneumonia, and bronchiolitis obliterans.

Patients hospitalized with pulmonary involvement in whom the diagnosis cannot be determined may require bronchoscopy, bronchial lavage, and possibly biopsy. If the clinical probability of PCP is high, treatment should begin before diagnostic bronchoscopy.

### Neurologic Involvement

Neurologic diseases are the initial manifestation of AIDS in 10 to 20% of patients. The frequency of neurologic complications increases over the course of HIV infection, with cross-sectional studies showing a 75 to 90% prevalence of neurologic disorders in patients with AIDS. The overall incidence rates of HIV-associated neurologic diseases and CNS opportunistic infections have been decreasing since the introduction of HAART, although this trend is expected to change as resistance to antiretroviral drugs emerges.

Neurologic complications in the HIV-infected patient may be caused by both direct effects of HIV infection on the CNS and opportunistic infections and neoplasms occurring as a result of immunosuppression. In the early stages of HIV infection, aseptic meningitis, herpes zoster radiculitis, and inflammatory demyelinating polyneuropathy are common. Later stages of HIV infection are associated with cognitive dysfunction, dementia, opportunistic infections, cancers, and sensory neuropathies. The most common AIDS-defining neurologic complications are HIV encephalopathy (dementia), *C. neoformans* infection, toxoplasmosis, and primary CNS lymphoma. Less common CNS complications include bacterial meningitis, histoplasmosis (usually disseminated), CMV infection, progressive multifocal leukoencephalopathy, herpes simplex virus (HSV) infection, neurosyphilis, and tuberculosis. Noninfectious CNS processes include CNS lymphoma, cerebrovascular accidents, and metabolic encephalopathies.

Clinical presentations in patients with serious neurologic complications can be nonspecific, making the diagnosis and disposition challenging. The most common clinical manifestations of CNS pathology are seizures, meningismus, focal neurologic deficits, altered mental status, and headache (new or persistent). Infection accounts for a majority of neurologic disorders and most often is accompanied by fever.

Patients with CD4+ cell counts greater than 200 cells/µL who present with fever and meningismus in the absence of focal neurologic deficits should have an immediate lumbar puncture performed. For those with focal deficits or new seizures, neuroimaging is recommended first, followed by lumbar puncture if neuroimaging is unrevealing. For patients with altered mental status or headache, diagnostic evaluation should proceed as in the non-HIV-infected population, with neuroimaging and lumbar puncture reserved for those cases in which another cause for the symptoms is not identified or with a clear indication for workup (e.g., patient complaint of “the worst headache of my life”). For patients with CD4+ cell counts less than 200 cells/µL, a more aggressive approach is advocated, with any of the aforementioned findings demanding emergent imaging, usually followed by lumbar puncture (Fig. 130-2).

Generally speaking, for those CNS processes that require immediate identification, CT without contrast is considered adequate. If the entire ED evaluation is unrevealing, more advanced diagnostic imaging should be pursued immediately, usually in an inpatient setting, if the patient’s symptoms are severe or if new neurologic findings are present. For all other cases, close follow-up is indicated with the patient’s primary provider, because it has been demonstrated that more subtle lesions may be identified by contrast CT scan or magnetic resonance imaging (MRI). Cerebrospinal fluid (CSF) analysis should include determination of opening and closing pressures, cell count, measurement of glucose and protein, Gram’s stain, and bacterial, viral, and fungal cultures. Testing for toxoplasmosis and cryptococcal antigens and coccidioidomycosis titer also are appropriate, particularly in patients with later-stage disease. A prudent measure is to direct the laboratory to hold excess CSF for further testing if the preliminary workup is unrevealing.

### HIV Encephalopathy

HIV encephalopathy, or *AIDS dementia complex*, occurs in up to one third of patients with HIV, and is the initial manifestation of AIDS in 3% of affected adults. It is a progressive process caused by direct HIV infection and commonly is heralded by impairment of recent memory or subtle cognitive deficits, such as difficulty concentrating. Traditionally, symptoms are expected to occur in patients with CD4+ counts less than 200 cells/µL, although since 1996, increasing numbers of cases are being seen in patients with CD4+ counts greater than 200 cells/µL.

Early stages of dementia may be easily confused with depression, the effects of psychoactive substances, or anxiety disorders. Deficits become more debilitating in later stages of disease and can include more obvious changes in mental status, seizures, frontal release signs, and hyperactive deep tendon reflexes; in such cases, physical examination usually reveals the hallmarks of advanced AIDS, including wasting, alopecia, generalized dermatitis, and lymphadenopathy. AIDS dementia is a diagnosis of exclusion: Even among patients with AIDS presenting to the ED with an established diagnosis of AIDS dementia, the appearance of progressive signs or symptoms requires immediate further evaluation to rule out other CNS processes. Neuroimaging findings in patients with HIV encephalopathy typically show atrophy and diffuse deep matter hyperintensities; MRI may reveal patchy punctate lesions in the white matter. Lumbar puncture findings typically are normal. Controlled trials in adults and children with HIV dementia have demonstrated benefit of high-dose zidovudine.

### Cryptococcus Neoformans Infection

*C. neoformans* is the agent of a fungal CNS infection that causes either focal cerebral lesions or diffuse meninoencephalitis. It occurs in up to 10% of patients with HIV infection but most commonly in those with CD4+ counts less than 100 cells/µL. The most frequent initial symptoms are fever and headache, often accompanied by nausea and vomiting. Less frequent manifestations are visual changes, dizziness, seizures, and cranial nerve deficits. The brainstem and basal ganglia are typical locations; high intracranial pressure and sudden clinical deterioration from herniation are relatively common. The mortality rate approaches 30%.

Patients with *C. neoformans* infection usually have no significant changes on CT. Definitive diagnosis relies on finding cryptococcal antigen in the CSF, which is nearly 100% sensitive and specific; other diagnostic tests include India ink staining (60 to 80% sensitive), fungal culture (95% sensitive), and serum cryptococcal antigen (95% sensitive). All patients with a positive result on serum cryptococcal antigen assay should undergo lumbar puncture to rule out neurologic involvement.
Additional findings associated with cryptococcal infection include elevated CSF opening pressure and a mononuclear pleocytosis. Treatment requires hospital admission for administration of intravenous amphotericin B (0.7 mg/kg per day) plus 5-flucytosine (100 mg/kg per day) for 2 weeks, followed by oral fluconazole (400 mg per day) for 8 weeks or until the CSF is sterile. The most clinically significant adverse effect of treatment for cryptococcal meningitis is bone marrow suppression due to flucytosine; amphotericin B also may cause fever and renal dysfunction. After successful treatment, chronic suppressive therapy with lower doses of oral fluconazole is indicated because of the high relapse rate (approximately 50%). This therapy can be discontinued in patients with immune reconstitution.

Toxoplasma Gondii Infection

* T. gondii is the most common cause of focal intracranial mass lesions in patients with HIV infection, with an incidence of 3 to 4%. In most cases, symptomatic disease is a result of reactivation of latent infection. Common signs and symptoms include headache, fever, altered mental status, and seizures. Focal neurologic deficits are found in up to 80% of cases. Serologic testing is not useful, because up to 30% of the U.S. population has antibodies to *T. gondii*. Diagnosis most often is made by the presence of multiple subcortical lesions on CT. Noncontrast CT often is used as the initial study in the ED, because addition of contrast has been shown to be of marginal value in patients with completely normal findings on noncontrast CT scans. In those patients with suspicious lesions, or those with clinical findings strongly suggestive of a pathologic process but equivocal or negative findings on noncontrast scans, a contrast CT or MRI study may be helpful. In the presence of contrast, toxoplasmosis lesions are ring-enhancing with surrounding edema. MRI is considered even more sensitive than contrast CT in delineating the extent of lesions but usually is not indicated in the ED setting.

Clinical and radiologic features often cannot reliably distinguish CNS toxoplasmosis from a wide variety of other potential causative disorders (e.g., lymphoma, cerebral tuberculosis, fungal infections, progressive multifocal leukoencephalopathy, CMV infection, KS, hemorrhage). Toxoplasmosis more typically is characterized by a greater number of lesions with a predilection for the basal ganglia and corticomedullary area, whereas lymphomas more often are singular lesions located in the periventricular matter or corpus callosum. Tuberculosis is characterized by an inflammatory appearance on the CT scan, with a thick isodense exudate filling the basal cisterns.

Patients with suspected toxoplasmosis should be hospitalized and treated with pyrimethamine (200 mg loading dose, then 50 to 75 mg/day) plus sulfadiazine (4 to 6 g/day). Folic acid (leucovorin, 10 mg/day) should be added to reduce the incidence of pancytopenia. Alternative agents to sulfadiazine include sulfisoxazole, clindamycin, azithromycin, atovaquone, and clindamycin.
or doxycycline and often are required due to the relatively high frequency of side effects associated with sulfadiazine. Dexamethasone (4 mg IV) may be used in cases with the radiographic finding of midline shift, critically elevated intracranial pressure (ICP), or clinical deterioration. Seizure prophylaxis is not recommended. Bacitracin is indicated for chronic suppressive therapy after initial treatment as well as for prophylaxis in patients with a positive result on serologic testing and a CD4+ cell count less than 100 cells/µL. Failure to respond to treatment suggests an alternate diagnosis, which may necessitate biopsy.

Primary Central Nervous System Lymphoma

A previously rare disorder, primary CNS lymphoma occurs in up to 5% of patients with HIV infection, typically in those with CD4+ cell counts less than 50 cells/µL. Incidence has decreased slightly since 1996 with the introduction of HAART. Primary CNS lymphomas originate from B cells that express Epstein-Barr virus (EBV). Patients present with headache, aphasia, memory loss, hemiparesis, or seizure. Diagnosis usually is based on CT findings, which show hyperdense or isodense round or multiple lesions that enhance with contrast, and have a predilection for the periventricular region. Differentiation from toxoplasmosis can be challenging and often is made after failure to respond to therapy for that infection. PCR assay for EBV is a helpful diagnostic adjunct, but definitive diagnosis often necessitates biopsy. Prognosis for lymphoma is poor, with median survival time of less than 1 month. Life expectancy may be extended to several months with whole-brain irradiation along with corticosteroids and chemotherapy.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy occurs in approximately 1 to 3% of patients with AIDS and is caused by reactivation of the polyomavirus (JC virus). The most common presenting features are weakness, speech disturbances, cognitive dysfunction, and headaches. CT or MRI scans show hypodense white matter disease. JC virus PCR assay is approximately 80% sensitive. Progressive multifocal leukoencephalopathy carries a poor prognosis unless immune reconstitution can occur.

Tuberculosis Meningitis

*Mycobacterium avium-intracellulare* (MAI) infection is the most common cause of tuberculous meningitis; it occurs in less than 1% of patients with AIDS and may be associated with intracranial abscesses or spinal cord abscesses. CT findings in MAI infection may suggest toxoplasmosis. Because findings on CSF analysis may be negative, definitive diagnosis often requires brain biopsy. Four-drug therapy for at least 9 months is required for cure.

Human Immunodeficiency Virus Neuropathy

HIV infection also is associated with a variety of disorders of the peripheral nervous system. These disorders rarely are emergent but necessitate appropriate referral. The most common peripheral nervous system disorder is HIV neuropathy, which occurs in up to 50% of HIV-infected patients and is characterized by painful sensory symptoms in the feet. Treatment in the ED should be directed toward analgesia. Ibuprofen may be used for first-line therapy, although narcotics may be required in more severe cases. Amitriptyline and phenytoin have been shown to be helpful but should be used judiciously because of their potential for causing delirium in patients with concurrent HIV dementia.

Gastrointestinal Involvement

Most patients with AIDS have gastrointestinal signs or symptoms at some time during the course of their illness. The most common clinical manifestations are diarrhea, weight loss, malabsorption, abdominal pain, bleeding, esophageal symptoms, and hepatobiliary symptoms. Nonspecific findings may include nausea, vomiting, and abdominal pain as common adverse effects of antiretroviral therapy. Evaluation for a specific causative disorder often is difficult until objective studies are performed. More than one source of infection often is present, which may further complicate the diagnosis. Treatment in the ED focuses on supportive care, fluid and electrolyte repletion, and obtaining appropriate studies for further investigation.

Oropharynx

Oral involvement is common in AIDS and may manifest as a variety of problems, including fungal infections (oral candidiasis, histoplasmosis, cryptocontocciosis, penicillinosis), viral lesions (herpes simplex, herpes zoster, cytomegalovirus, hairy leukoplakia, papillomavirus infection), bacterial lesions (periodontal disease, necrotizing stomatitis, tuberculosis, *Mycobacterium avium* complex [MAC], bacillary angiomatosis), neoplasms (Kaposi's sarcoma, lymphoma, Hodgkin's lymphoma), and autoimmune or idiopathic lesions (salivary gland disease, aphthous ulcers). Presence of oral lesions may be an indicator of disease progression.

Oral candidiasis affects more than 80% of patients with AIDS. *Candida albicans* infection, the most common fungal infection in HIV-infected patients, typically involves the tongue and buccal mucosa and may be asymptomatic. Symptoms may include soreness, burning, and dysphagia. Candidiasis can be distinguished from hairy leukoplakia by its characteristic whitish, lacy plaques, which are easily scraped away from an erythematous base. Any of three forms of candidiasis may be seen: pseudomembranous candidiasis (thrush), erythematous candidiasis, and angular cheilitis. Microscopic examination with a potassium hydroxide smear can confirm the diagnosis in the ED. Most oral lesions can be managed symptomatically on an outpatient basis. Preferred treatment is with clotrimazole troches, 10 mg, PO, five times daily for 14 days. Other treatment options include nystatin vaginal tablets, one tablet dissolved slowly in the mouth four times daily, and nystatin pastilles, two dissolved in the mouth five times daily. Systemic therapy with fluconazole, ketoconazole, or itraconazole may be used for resistant lesions.

Hairy leukoplakia also is commonly seen, typically manifesting as white, corrugated or filiform, thickened lesions on the lateral aspects of the tongue. Because it often is asymptomatic, therapy is not necessary, but when indicated, treatment is with acyclovir, 800 mg PO five times a day for 2 to 3 weeks.

Painful oral and perioral ulcerations may be caused by HSV. HSV infection can be diagnosed in the ED by the identification of multinucleated giant cells in scrapings of the lesions. Definitive diagnosis is by culture. Therapy is with acyclovir, 400 mg PO three times daily for 7 to 10 days. MAC also may cause painful oral ulcerative lesions. Diagnosis is by acid-fast stain. Oral Kaposi's sarcoma may appear as nontender, well-circumscribed, slightly raised, violaceous or erythematous lesions anywhere in the oropharynx. Definitive diagnosis requires biopsy. Treatment may include surgical excision, localized chemotherapy, sclerosing agents, or radiation therapy.

Periodontal disease, including gingival erythema and necrotizing periodontal disease, may be seen in up to 10% of
patients. Outpatient treatment, including local irrigation and mouth rinses and oral antibiotics such as amoxicillin-clavulanate or clindamycin, may be instituted. Dental follow-up care is essential.

Aphthous ulcers, often painful and recurrent, are small crateriform ulcers with white to yellow membranes surrounded by an erythematous ulcer. The etiology is unknown but is thought to involve immune deficiency. Other potential causes of ulcers, such as fungal or mycobacterial infection, HSV or CMV infection, and lymphoma, should be excluded. Aphthous ulcers usually respond to topical steroids, such as 0.05% fluclonamide ointment mixed 50-50 with an oral topical anesthetic such as benzocaine preparations (e.g., Orabase).

Esophagus

In HIV infected patients with dysphagia or odynophagia and a CD4+ count greater than 200 cells/µL, non-HIV-related causes of esophagitis, such as gastroesophageal reflux disease or medications, must be considered. In patients with a CD4+ count below 200 cells/µL, Candida is responsible for 50 to 70% of esophagitis cases. Other etiologic disorders include HSV and CMV infection, Kaposi’s sarcoma, Mycobacterium avium complex disease, and reflux esophagitis, as well as idiopathic esophagitis.

The most cost-effective approach to the evaluation of patients with esophageal complaints is to initiate empirical therapy with fluconazole (100 to 200 mg PO daily for 2 to 3 weeks). Alternative agents include clotrimazole, ketoconazole, and itraconazole. Endoscopy, fungal stains, viral cultures, and occasionally biopsy may be required to definitively establish diagnosis in nonresponders. On endoscopy, Candida infection is associated with an ulcerative pattern with plaques separated by normal mucosa compared with herpes, which typically produces “punched-out” ulcerations without plaques.

Relapses are common after cessation of treatment, and intravenous amphotericin B is recommended in these cases. Disseminated candidiasis is managed with intravenous amphotericin B and fluconazole. Fluconazole has been shown to be effective for prophylaxis against fungal infections in patients with a CD4+ count less than 100/µL, although survival is unaffected by prophylactic therapy.55

Diarrhea

Diarrhea is the most common gastrointestinal complaint in AIDS, occurring in 50 to 90% of patients. Diarrhea can vary in severity, ranging from a few loose stools per day to massive fluid loss with prostration, fever, chills, and weight loss. Medication side effects should be considered, because use of antiretroviral agents is associated with a high incidence of gastrointestinal adverse effects. Potential pathogens include parasites (Cryptosporidium parvum, Enterocytozoon bieneusi, Isospora belli, Giardia lamblia, Entamoeba histolytica, Microsporidia, Cyclospora, and others), bacteria (Salmonella, Shigella, Campylobacter, Helicobacter pylori, MTB, Mycobacterium avium complex, Clostridium difficile, and others), viruses (CMV, herpes simplex virus, HIV, and others), and fungi (Histoplasma capsulatum, Cryptococcus neoformans, Coccidioides immitis, and others). Opportunistic infections are more commonly seen among patients with CD4+ cell counts less than 100 cells/µL. Significant gastrointestinal bleeding and dehydration have been associated with many pathogens, particularly CMV. Salmonella infection can be of particular concern in HIV-infected patients because it often produces recurrent bacteremia. Neoplastic gastrointestinal tract involvement with Kaposi’s sarcoma or lymphoma may produce dysphagia, obstruction, intussusception, or diarrhea.

ED management of diarrhea should be directed toward stabilization, hydration, and obtaining appropriate diagnostic studies. Initial studies should include blood cultures (for MAC and salmonellae), stool cultures, microscopic examination of stool for ova and parasites, trichrome stain for microsporidia, Giardia EIA, and C. difficile assay for toxins A and B. If indicated, colonoscopy or sigmoidoscopy (with or without biopsy) may be arranged for patients who require further evaluation.56 Often, no definitive diagnosis of the cause of diarrhea can be made in patients with AIDS. Management of severe diarrhea not necessitating specific therapy may include attapulgite (Kaopectate), psyllium (Metamucil), diet modification, or diphenoxylate hydrochloride with atropine (Lomotil).

Cryptosporidium and Isospora infections commonly are associated with HIV infection, and both organisms may produce prolonged watery diarrhea.57 Diagnosis may be sought using acid-fast staining of stool samples, monoclonal antibody assay, or ELISA. Treatment of these disorders is variably successful. Symptoms may be managed with diet modification or loperamide. Cryptosporidium infections may be treated with some success using paromomycin or azithromycin. Isospora infections often are successfully treated with TMP-SMX. Pyrimethamine or metronidazole may be used as alternative agents. HAART also may reduce duration and severity of symptomatology.

Viruses causing diarrhea include CMV, adenovirus, rotavirus, and others.58 CMV colitis most commonly is seen in patients with CD4+ cell counts below 50 cells/µL. Diarrhea is associated with weight loss and abdominal pain; CT shows colonic thickening. Complications include hemorrhage and perforation. Treatment is with intravenous ganciclovir, valganciclovir, or foscarnet.

C. difficile is responsible for approximately 50% of cases of diarrhea in HIV-infected patients. The typical history is one of watery diarrhea and recent antibiotic use. C. difficile testing should be performed. Treatment is with oral metronidazole (Flagyl) or vancomycin.

MAC consists of M. avium and M. intracellularle, acquired by ingestion or inhalation. The typical presentation is that of fever, night sweats, and diarrhea in patients with CD4+ counts less than 100 cells/µL. Diagnosis can be made by stool or blood cultures, results of which may take up to weeks to turn positive. Treatment is with oral clarithromycin, 500 mg twice a day, plus ethambutol, 15 mg/kg per day. Prophylaxis is indicated in patients with CD4+ cell counts less than 50 cells/µL.

Malabsorption syndromes are relatively common with HIV infection. Delayed gastric emptying and intestinal infections may contribute and lead to significant weight loss. Treatment includes nutritional counseling, parenteral nutrition, and adjunctive agents such as dronabinol, megestrol acetate, and human growth hormone.59

Liver Involvement

Hepatomegaly is seen in up to 50% of patients with AIDS. Jaundice is less common. Hepatitis B and hepatitis C are common among these patients, especially among intravenous drug users. Previous hepatitis B virus infection may become reactivated after HIV infection or may be acquired with increased frequency after HIV infection. Several opportunistic organisms, including CMV, MAI, M. tuberculosis, Histoplasma capsulatum, and Cryptosporidium, also can produce hepatitis-like disease in patients with HIV infection. Typically, an elevation in the alkaline phosphatase level occurs that is disproportionate to levels of other liver enzymes. Hepatotoxicity also may result from a variety of medications, including indinavir.
Complete examination of the anus and rectum is important in diagnosing such disorders. Fissures, masses, infection, and inflammation will be detected by inspection, palpation, digital examination, anoscopy, and, when indicated, sigmoidoscopy. Proctocolitis is common in patients with AIDS and may be caused by any of several organisms, including Campylobacter jejuni, Shigella species, Salmonella species, Giardia, HSV, Entamoeba histolytica, Chlamydia, and Neisseria gonorrhoeae. Diagnostic tests include anoscopy with evaluation of stool for blood, leukocytes, ova, and parasites. Additionally, bacterial cultures, an HSV culture or Tzanck preparation, a rapid plasma reagin (RPR) test, and appropriate assays for detection of N. gonorrhoeae and Chlamydia may be useful. The diagnosis of anal gonorrhea can be confirmed on a Gram’s stain of stool showing leukocytes and intracellular organisms. HSV infection can be diagnosed by viral cultures or by identification of multinucleated giant cells on scrapings of anal lesions.

Cutaneous Involvement

Several common cutaneous manifestations of AIDS are likely to be seen in the ED. Preexisting dermatologic conditions may be exacerbated by HIV infection. Common infections and conditions may manifest in an atypical fashion. Generalized cutaneous complaints such as xerosis (dry skin) and pruritus are common and may be manifested before an AIDS-defining illness. Treatment for these conditions is identical to that in patients who do not have AIDS. Xerosis may be treated with emollients. Pruritus may be treated with oatmeal baths and, if necessary, antihistamines.

Kaposi’s sarcoma is the second most common manifestation of AIDS. It is found commonly among homosexual or bisexual men and is caused by human herpesvirus-8 (HHV-8). The disease usually is widely disseminated with mucous membrane involvement. Kaposi’s sarcoma typically manifests in HIV-infected patients with any variation of mucocutaneous involvement, lymph node involvement, or involvement of the gastrointestinal tract or other organs. The typical appearance includes pink, red, or purple papules, plaques, nodules, and tumors. Treatment is based on site and extent of involvement. Kaposi’s sarcoma is incurable but rarely is fatal. Palliative therapies include cryotherapy, radiotherapy, infrared coagulation, sclerosing agents, intralesional vinblastine, and systemic chemotherapy with doxorubicin (Adriamycin), bleomycin, and vincristine.63

Varicella-zoster (VZ) eruptions are nearly 27 times more likely in HIV-infected patients than the general population, and multidermalatomal involvement is more frequent in those with AIDS.64 In the HIV-infected patient with simple dermatomal zoster infection, outpatient management options include oral foscarnet (500 mg three times a day), acyclovir (800 mg fives times daily), and valacyclovir (1000 mg three times daily).65 Hospital admission to an isolation bed for administration of intravenous acyclovir (10 mg/kg every 8 hours) is warranted for any patient with systemic involvement, ophthalmic zoster, or severe dermatomal zoster.66 Varicella immune globulin may be useful in patients with primary infection and visceral involvement.

HSV infections are highly prevalent among HIV-infected patients. Both HSV-1 and HSV-2 infections may occur as localized infection or systemic disease. HSV infections commonly manifest with fever, adenopathy, malaise, and ulcerative lesions of mucosal and cutaneous sites. Common sites of involvement include oral mucosa, genital areas, and rectum. HSV and HZV infections may be difficult to distinguish clinically, and cultures may be required for differentiation of the two conditions. Reactivation is common. Mucocutaneous HSV infection responds well to oral famciclovir (750 mg three times daily) or acyclovir (200 mg five times daily for 10 days). For disseminated infection or neurologic involvement, intravenous acyclovir is recommended (5 to 10 mg/kg every 8 hours for 7 to 21 days). Famciclovir, penciclovir, foscarnet, or valacyclovir also may be used. Suppressive therapy is effective in decreasing rates of recurrence. Patients with these viral infections should be assigned to isolation beds in the hospital.

Molluscum contagiosum manifests with small flesh-colored papules with a whitish core (see Fig. 151-4). The condition is difficult to cure; cryotherapy or curettage is reserved for symptomatic lesions. Intertriginous infections with either Candida or Trichophyton are common and may be diagnosed by microscopic examination of scrapings in potassium hydroxide. Treatment may include topical imidazole creams (e.g., clotrimazole, miconazole, ketoconazole). Scabies should be considered in all HIV-infected patients, particularly those with dermatitis complicated by excoriations or pruritus. Microscopic identification of mites is diagnostic. Preferred treatment is with single application 5% permethrin. Sexual and household contacts also should be treated. Norwegian scabies is particularly resistant to treatment and should be considered if lesions consistent with scabies fail to respond to traditional therapy. Treatment should be undertaken in consultation with an infectious disease specialist.

Seborrheic dermatitis is common, particularly among patients with AIDS-associated dementia. Lesions are erythematous, hyperkeratotic scaling plaques involving the scalp, face (especially the nasolabial folds), ears, chest, and genitalia. Treatment with topical steroids often is effective, although less so than in the general population. Alternative therapy includes topical or oral ketoconazole.

Human papillomavirus infections occur with increased frequency in immunocompromised patients. Treatment is cosmetic or symptomatic and may include cryotherapy, topical agents, or, in extreme cases, laser therapy.

Other dermatologic disorders, including psoriasis, atopic dermatitis, and alopecia, occur with increased frequency in patients with AIDS. Any preexisting dermatologic disorder may be exacerbated by HIV infection.

Ophthalmologic Manifestations

Ocular findings are common in the HIV-infected patient. Cotton-wool spots in the retina are the most common eye finding and do not require intervention. Other common ophthalmologic manifestations of HIV include CMV retinitis, herpes zoster ophthalmicus, and Kaposi’s sarcoma of eyelids or conjunctiva.

CMV retinitis occurs in 10 to 30% of HIV-infected patients and is the most common cause of blindness in patients with AIDS. With advances in HAART, reduced incidences of CMV retinitis have been observed, but discontinuation of HAART may result in intraocular inflammation.67 CMV retinitis typically produces severe necrotic vasculitis and retinitis. This may be asymptomatic or may manifest as blurred vision, a change in visual acuity, “floaters,” flashes of light, photophobia, scotoma, redness, or pain.68 Funduscopic examination typically shows fluffy white perivascular lesions with areas of hemorrhage that may be confused with retinal cotton-wool spots, a benign condition with no prognostic implications for those with AIDS. Considerations in the differential diagnosis also include toxoplasmosis, syphilis, HSV infection, VZV infection, and tuberculosis. Because of the risk of rapid progression and blindness, any patient in whom ophthalmic CMV
infection is a possibility requires immediate evaluation by an ophthalmologist. Treatment is with intravenous ganciclovir (5 mg/kg every 12 hours for 2 weeks, followed by 6 mg/kg/day maintenance therapy) or foscarit (90 mg/kg every 12 hours). Intravitreal injections of fomiviren also may be used for patients unresponsive to traditional therapy. 55 Similar rates of efficacy are achieved with ganciclovir and foscarit. Ganciclovir-containing intravitreal implants constitute another therapeutic option that provides higher intravitreal concentrations and is associated with reduced risk for CMV-related retinal detachment. Immune recovery uveitis may occur as a complication of treatment during the recovery phase. 66 Chronic suppressive therapy with ganciclovir or foscarit may be indicated. Patients with serum anti-Toxoplasma antibodies and CD4+ cell counts below 100 cells/μL should receive prophylaxis with TMP-SMX. 68 Herpes zoster ophthalmicus is another common cause of ocular damage in patients with HIV infection. The typical presentation is pain or paresthesia in the distribution of cranial nerve V1, followed by the emergence of the vesicular zoster skin rash. Complications include conjunctivitis, episcleritis, iritis, keratitis, secondary glaucoma, and, rarely, retinitis. As with CMV infection, early recognition and treatment can prevent morbidity. All patients with suspected zoster ophthalmicus require immediate ophthalmologic consultation and may need hospital admission. Treatment should be initiated with oral or intravenous acyclovir, famciclovir, or valacyclovir.

Cardiovascular Manifestations

Cardiac manifestations of AIDS may include pericardial effusion, cardiomyopathy, increased left ventricular mass, myocarditis, endocarditis, malignancy, and cardiotoxicity of medications. 69 The pericardium is the most common site of cardiac involvement, although many patients have clinically insignificant effusions. Pericardial effusions may be secondary to malignancies, uremia, lymphatic obstruction, or infections such as with Mycobacterium tuberculosis, Streptococcus pneumoniae, Staphylococcus aureus, or a host of other bacterial, viral, fungal, or protozoal pathogens. Infective endocarditis occurs commonly in HIV-infected patients with a history of intravenous drug use and should be considered in all injection drug users presenting with febrile illnesses. Cardiac neoplasms also may occur, typically as either Kaposi’s sarcoma or lymphoma. Such neoplasms may be clinically silent or may manifest congestive heart failure, tamponade, or arrhythmias or other clinical syndromes. Some antiretroviral agents are associated with a fat redistribution syndrome and diabetes, which may increase the risk of coronary artery disease. Patients with HIV infection also have higher rates of dilated cardiomyopathy. Etiologic categories include primary HIV infection; viral, mycobacterial, fungal, or protozoal infection; drug-induced; immunologic; and ischemic. Patients present with typical signs and symptoms of congestive heart failure; echocardiography shows left ventricular diastolic dysfunction with decreased ejection fraction. These patients are at an increased risk for arrhythmias.

Renal Manifestations

Renal insufficiency in the patient with AIDS may be associated with a variety of underlying disorders, but initial ED presentation may include general malaise, edema, or oliguria. Prerenal azotemia is the most common renal abnormality, especially in conjunction with volume loss related to systemic or gastrointestinal infection. It is diagnosed and treated by evaluation and therapy of fluid status. Acute renal failure also may occur and is often secondary to drug nephrotoxicity (e.g., from pentamidine, aminoglycosides, sulfura drugs, foscarit, rifampin, dapsone, or amphotericin B). HIV-associated nephropathy (HIVAN) typically is a cause of chronic renal insufficiency in the late stages of immunosuppression, but may occur earlier in disease progression. 70 Vasculitis, tuberculosis, or other systemic infections also may contribute to renal insufficiency. Postrenal azotemia may result from tubular, ureteral, or pelvis obstruction or from lymphoma, stones, fungus ball, blood clot, or sloughed papillae. ED evaluation should include urinalysis, assessment of fluid status, and determination of blood urea nitrogen and serum creatinine. If indicated, ultrasonography or intravenous pyelography may demonstrate the site and degree of obstruction. Renal biopsy may be indicated for patients with proteinuria and undiagnosed renal disease. Treatment depends on the causative agent. Therapies that have demonstrated limited benefit in HIVAN include corticosteroids, angiotensin-converting enzyme inhibitors, and dialysis and should be initiated in consultation with a nephrologist.

Psychiatric Considerations

HIV-infected patients may present with a variety of social and emotional issues complicated by neuropsychiatric and cognitive changes. The diagnosis of AIDS may dramatically alter interactions with family and friends, and patients may be devastated by the prospect of confronting chronic illness and death. Although psychiatric issues are common among HIV-infected patients, many do not receive optimal care. 71 Depression is common among AIDS patients and often is responsive to hospitalization and psychosocial intervention. It has been estimated that 60% of HIV-infected patients experience depression during their illness. 72 Patients with depression generally have lower CD4+ counts and may report more AIDS-related symptoms. 72 Referral for antidepressant therapy should be considered if symptoms have lasted for longer than 2 weeks. Depression may result in suicidal ideation and may bring the patient to the attention of the ED for medical treatment after a suicide attempt. Other psychiatric disorders may be seen, including personality disorders, addiction disorders, and adjustment disorders.

Delirium suggests the presence of a primary physiologic disease state. Considerations in the differential diagnosis include CNS, toxic, and metabolic derangements. AIDS psychosis commonly manifests with psychiatric symptoms such as hallucinations, delusions, or other abnormal behavioral changes. Treatment should be undertaken with traditional antipsychotic agents.

Sexually Transmitted Diseases

Sexually transmitted diseases (STDs) are common among HIV-infected patients, and the prevalence of STDs, including syphilis, is increasing. 73 Syphilis is associated with increased susceptibility to HIV seroconversion by an unknown mechanism. 74 For EDs that are able to institute screening for HIV, combined testing for both HIV and other STDs may be most cost-effective. 75 Common STDs include gonorrhea, chlamydial infection, herpes, and syphilis. Serologic testing for syphilis should be performed for all HIV-infected patients with a suspected STD. Empirical therapy for syphilis may be instituted even without laboratory proof of infection. Recommended treatment for primary or secondary syphilis of less than 12 months’ duration is with a single intramuscular dose of benzathine penicillin (2.4 million units). For latent syphilis or unknown
duration of secondary syphilis, three weekly injections are recommended. Patients with known or suspected syphilis should be evaluated for the presence of neurosyphilis, which has an increasing incidence among HIV-infected persons. Patients with neurosyphilis should be treated with penicillin G, 12 to 24 million units IV daily for 10 to 14 days.

**Hematologic Complications**

Hematopoiesis may be adversely affected by HIV infection, tumor, infection, or HIV medications. Anemia in AIDS is independently associated with an increased risk of death. Chronic anemia in AIDS characteristically is of the normocytic, normochromic type, with a low reticulocyte count and low erythropoietin level. HAART usually results in improvement.

**Pediatric Considerations**

HIV/AIDS in pediatric patients may have a variety of ED presentations, including recurrent or severe bacterial infections, chronic diarrhea, candidiasis, opportunistic infections, and numerous other clinical syndromes. In addition to stabilization, diagnostic tests, and definitive management, close follow-up and communication with family members and primary physicians are imperative in this population.

**Drug Reactions**

Drug reactions are extremely common among HIV-infected patients; these patients commonly are treated with a variety of drugs known to produce adverse effects in some people. In addition, for unclear reasons, HIV-infected persons often experience more frequent or more severe reactions to commonly used medications than noninfected patients. Dermatologic reactions are particularly common. Antimicrobial drugs frequently are implicated. Drug reactions must always be considered as a possible cause of new symptoms in HIV-infected patients. Table 130-2 presents a brief summary of common drug reactions in the HIV-infected patient.

---

**MANAGEMENT**

**Antiretroviral Therapy and Chemoprophylaxis**

The introduction of HAART in 1996 has had dramatic effects on the clinical consequences of HIV infection in the developed world. The incidence of AIDS-defining illnesses and death rate declined rapidly through 1998. Reports of high levels of treatment failure due to serious adverse effects, emergence of drug resistance, and difficulties in maintaining long-term adherence have raised concerns regarding the continued success of HAART; however, recent studies suggest that the reduction in morbidity and mortality associated with HAART has been sustained. The U.S. Department of Health and Human Services (DHHS) has published guidelines for use of antiretroviral agents in HIV-infected adults and adolescents.

Antiretroviral therapy for HIV infection is constantly evolving, and optimal decisions regarding such therapy will require a basic understanding of the classes of drugs available, the rationale for initiating treatment, and the common adverse drug reactions. The five classes of antiretroviral drugs currently in use are listed in Table 130-3. Each class of drugs independently interrupts the normal life cycle of the HIV. When used with appropriate timing and in combination, these agents have been shown to significantly delay progression of disease and prolong life.

The first drug demonstrated to have antiretroviral activity was a nucleoside analogue reverse transcriptase inhibitor (NRTI), a competitive inhibitor of the viral enzyme reverse transcriptase. Several controlled trials showed that zidovudine (azidothymidine [AZT], Retrovir) decreases the number and severity of opportunistic infections. Although zidovudine also was found to decrease the rate of AIDS progression in patients with early symptomatic HIV infection, no significant change in survival was found. This finding, coupled with the recognition of the emergence of drug resistance and the appearance of significant side effects, led to the development of other NRTIs. Combination therapy, with zidovudine and another NRTI, resulted in not only prevention of disease progression but also decreased mortality. The FDA has since approved multiple agents in this class, each with its own unique adverse effect profile. The most common side effects are bone marrow suppression with zidovudine; distal sensory peripheral neuropathy with didanosine (Videx), stavudine (Zerit), and zalcitabine (Hivid); and pancreatitis with didanosine.

The non-nucleoside reverse transcriptase inhibitors (NNRTIs) are noncompetitive inhibitors of reverse transcriptase and block RNA-dependent and deoxyribonucleic acid (DNA)–dependent DNA polymerase activity. Three NNRTIs are currently available; the most commonly used agents are nevirapine (Viramune) and efavirenz (Sustiva). Target organ-

* Protease inhibitors
* Entry inhibitors
* Integrate inhibitor
isms have a high propensity for developing resistance to these agents, which are recommended for use only as part of a three-drug (or more) regimen. Rash is the most common side effect associated with use of the NNRTIs, with the development of Stevens-Johnson syndrome seen in a small minority of patients (less than 5%). Symptomatic hepatitis, including fatal hepatic necrosis, has been reported with use of nevirapine.

The enzyme HIV-1 protease activates the HIV proteins that are required for infectivity by cleaving the inactive viral polyprotein precursors. Protease-inhibiting agents block this step, thereby preventing HIV particles from becoming infectious. Ten protease inhibitors currently are approved for clinical use in the United States. Introduction of this class of drugs is believed to be responsible in large part for the marked decline in mortality rates for HIV infection, which was first realized in 1996. Protease inhibitors are expensive, however, and they also have been associated with a high frequency of side effects. Short-term effects are principally gastrointestinal (including nausea, diarrhea, and bloating); long-term effects are metabolic, the most common of which are hyperglycemia, hyperlipidemia, and fat redistribution.

Additional newer classes of drugs include entry inhibitors and integrase inhibitors. Entry inhibitors prevent HIV entry into cells by targeting specific viral surface proteins or their corresponding receptors. Enfuvirtide and maraviroc are two entry inhibitors currently approved for use in combination with other antiviral agents only in treatment-experienced patients. Major side effects include local injection site reactions and increased rate of bacterial pneumonia (with enfuvirtide). Integrase inhibitors work by blocking integrase, a protein required by HIV to allow it to insert its viral genetic material into the genetic material of an infected cell. Raltegravir is the only integrase inhibitor currently approved for use, restricted to patients who have limited or no treatment options. Common side effects include diarrhea, nausea, headache, and fever.

The DHHS recently published updated guidelines for use of antiretroviral agents in HIV-infected adults and adolescents. In general, the goals of antiretroviral therapy are virologic, immunologic, clinical, and therapeutic. Because virologic (HIV RNA levels) and immunologic (CD4+ cell count) parameters are independent predictors of clinical outcomes, therapeutic recommendations are based on both of these factors. The virologic goal is to reduce viral load as much as possible, halt disease progression, and prevent development of resistant HIV variants. Immunologic goals are to achieve both quantitative (CD4+ cell count) and qualitative (pathogen-specific immune response) immune reconstitution. The principal clinical goals are to prolong and improve the quality of life. The therapeutic goal is to achieve the other three goals by choosing a sequence of drugs that maintains therapeutic options, minimizes side effects, and optimizes the likelihood of patient compliance with the chosen regimen.

Expert consensus on the timing of initiation of HAART continues to evolve. The current consensus recommends mandatory treatment for HIV-infected patients with CD4+ counts below 350 cells/µL or with history of AIDS-defining illness. Other patient populations in whom initiation of antiretroviral therapy is indicated regardless of CD4+ count include pregnant women, patients with HIVAN, and patients with HBV coinfection requiring treatment. Similarly, in patients with recognized primary HIV infection, antiretroviral therapy is recommended, because early treatment is believed to decrease the number of infected cells, maintain or restore immune response, and perhaps lower the viral “set point,” resulting in improved course of the disease. Therapy may be considered in some patients with CD4+ greater than 350 cells/µL, given some evidence suggesting that higher CD4+ counts can be achieved with early therapy; however, initiation of treatment in these patients should be individualized in accordance with the willingness and readiness of the person to begin therapy, the potential benefits and risks of initiating therapy in an asymptomatic person, and the likelihood of compliance with the prescribed treatment regimen.

Selection of an appropriate combination of drugs also is a complex issue for which no definitive recommendations exist. Twenty-eight antiretroviral drugs are currently approved by the FDA. A complete list and up-to-date guide for their use can be found on the NIH website (AIDSinfo.nih.gov). The current DHHS recommended first-line HAART regimens include NNRTI-based regimens (one NNRTI and two NRTIs), or protease-inhibitor–based regimens (one or two protease inhibitors and two NRTIs). Triple-NRTI regimens are recommended as second-line regimens. Therapy should be individualized with consideration of tolerability, comorbid conditions, adverse effect profile, likely drug-drug interactions, convenience, and likelihood of adherence.

Pregnancy should not preclude women from receiving optimal treatment regimens; however, issues relating to prevention of mother-to-child transmission as well as maternal and fetal safety deserve special considerations. Previous studies have shown that HAART reduces perinatal transmission to 1 to 2%, and the rate is strongly correlated with viral load at the time of delivery. On the basis of these observations, HAART should be recommended for any pregnant woman. Selection of antiretroviral combinations should take into account known safety efficacy and pharmacokinetic data for each agent during pregnancy. Efavirenz-containing regimens should be avoided in pregnancy or in women of reproductive age owing to potential teratogenic effects. Elective cesarean section has established merit in reducing perinatal transmission if done at 38 weeks of gestation with a maternal viral load greater than 1000 copies/mL.

The goal of the antiretroviral therapy is to produce long-term viral suppression. Clinical situations that should prompt consideration for changing therapy include drug toxicity or intolerance, difficulty with adherence, and failure to suppress viral infection. Decisions regarding alternative treatment regimens should be made in consultation with infectious disease experts to assess potential cross resistance from previously used drugs. With advances in genotypic and phenotypic analysis of HIV strains, selection of a drug regimen based on drug resistance patterns will soon become an essential part of therapeutic decision-making.

Chemoprophylaxis is directed toward preventing initial and subsequent episodes of certain opportunistic infections (i.e., primary and secondary prophylaxis). Emphasis on measures to prevent opportunistic infections is critical because of the inherent limitations of HAART and the recognition that these infections constitute a cause of significant morbidity and mortality in the HIV-positive population. The CD4+ cell count is the best predictor of the risk for opportunistic infections and is used most often in making decisions about initiating or maintaining antimicrobial prophylaxis. The most serious and common infections for which antimicrobial prophylaxis has been shown to be effective include PCP, toxoplasmosis, tuberculosis, and MAC infection. Specific timing and choice of agents are described in earlier clinical sections of this chapter; a more comprehensive review can be found in the Public Health Service and Infectious Disease Society Revised Guidelines for the Prevention of Opportunistic Infections. The emergency physician can play a critical role in recognizing those patients requiring initiation of chemoprophylaxis and then should work closely with the patient's
primary care doctors or an infectious disease consultant to begin therapy.

**Immunizations for Human Immunodeficiency Virus–Infected Patients**

Response to immunizations may be variable among HIV-infected patients. Many such patients mount an adequate antibody response to immunizations, but the immune response is not predictable.\(^\text{90}\) Most routine immunizations recommendations are the same as for the non-HIV-infected patients.\(^\text{91}\) However, HIV-infected patients should not receive live virus or live bacterial vaccines. Pneumococcal vaccine is recommended for all patients older than 2 years of age\(^\text{92}\); however, immunization is recommended early in the disease course to optimize antibody development.\(^\text{93}\) Hepatitis B vaccine is indicated for patients at risk of exposure, although owing to variable immune response, follow-up serologic testing is indicated. Hepatitis A vaccination also should be considered because of increased risk of severe liver damage among patients previously infected with hepatitis B or C.\(^\text{94}\) Influenza vaccination is considered safe and is routinely recommended.\(^\text{95}\) Measles-mumps-rubella (MMR) vaccine may be considered because studies have not documented an increased incidence of adverse effects. If polio vaccine is indicated, enhanced inactivated polio vaccine may be administered. Although evidence suggests that the expression of HIV may be transiently increased by administration of tetanus toxoid,\(^\text{96}\) the clinical significance of this observation is unknown; current recommendations include providing a booster every 10 years for patients who have completed their primary series. Because the smallpox vaccine has not been rigorously studied in the HIV-infected population, the adverse effects and immune response are unknown, and some experts currently advise against its use.\(^\text{97}\)

The potential risks and benefits of immunization in the HIV-infected patient should be considered in decisions regarding immunization.

**DISPOSITION**

When questions remain about specific diagnostic or management options, consultation with specialists is appropriate. Consultations with an infectious disease specialist, neurologist, psychiatrist, AIDS specialist, and others may be indicated. Although asymptomatic patients are cared for predominantly by AIDS specialists, the increasing numbers of symptomatic patients are shifting the focus of primary care to nonspecialists.

Disposition decisions for HIV-infected patients are based, as for any patient, on clinical condition, availability of outpatient resources, and ability to arrange adequate follow-up observation. Any patient to be discharged must demonstrate capability for self-care or have sufficient in-home assistance available. In the AIDS population, particular attention should be given to ability to ambulate and to tolerate oral intake, as well as availability of timely and appropriate medical follow-up care.

Although the AIDS epidemic has raised concerns regarding the economic impact of the disease, financial considerations should not be a factor in determining management or disposition. Guidelines for hospital admission and discharge are presented in Box 130-3.

**ETHICAL CONSIDERATIONS**

Numerous ethical issues arise in the management of HIV-infected patients. General issues relevant to many patients may include issues of confidentiality, discrimination, access to health care, justice, informed consent, respect for autonomy, and advance directives. Additionally, concerns specific to HIV infection may arise, such as questions related to prenatal testing, abortion, euthanasia, suicide, access to experimental therapies, and role in clinical trials. In general, commonly accepted principles of medical ethics may be applied, which include principles of beneficence, nonmaleficence, respect for autonomy, and justice. Additionally, codes of ethical conduct developed by the define and the Society for Academic Emergency Medicine (SAEM) may provide general guidance.\(^\text{98,99}\)

Testing of patients to detect HIV infection has some controversial aspects. Routine HIV testing initiated in the ED often is not appropriate because of difficulties in ensuring appropriate pre- and post-test counseling and confidentiality issues. However, recommendations and referral for testing often are indicated for patients with risk factors or with clinical evidence of HIV infection. Each institution should have appropriate mechanisms arranged for these referrals.

Occupational exposures to blood and body fluids may necessitate testing of patients and health care workers in the ED to expedite initiation of antiretroviral therapy. In such cases, institutions not only must comply with state guidelines but should implement uniform policies and procedures for testing that ensure pretest and post-test counseling and confidentiality of results.

Confidentiality of the patient’s identity and medical data are of paramount importance in the ED, particularly for HIV-infected patients, for whom breached confidentiality may have numerous clinical, social, psychological, career, and insurability effects.

Public health responsibilities may at times override the duty of the physician to maintain strict confidentiality. AIDS is a reportable disease in most states, and state guidelines for reporting should be followed as a public health measure, even if this breaches confidentiality, as in cases of child abuse, gunshot wounds, or other infectious diseases. Moreover, the physician who is aware of potentially contagious practices of an infected patient has an obligation to provide appropriate counseling for that person. Additionally, infected patients should be encouraged to divulge their disease state with sexual or needle-sharing partners. In many states, the physician has the discretion to inform public health officials about the culpable practices, to allow partners potentially at risk to be informed.\(^\text{100}\)

The potential value of aggressive interventions in critical care settings must be determined on an individual case basis. Some clinicians believe that in the advanced stages of AIDS, resuscitative measures are not appropriate because of the uniformly poor prognosis. Many patients may agree as they approach the terminal stages of their disease. Appropriate advance directives should be completed before the patient...
enters the resuscitation setting. However, many patients fail to provide such documentation. Decisions regarding the withholding of extraordinary resuscitation efforts may be difficult to make in the ED because of insufficient information about an individual patient, his or her wishes, the specific disease state, prognosis, and the judgment and intentions of the primary care and consultant physicians. Although some ethicists argue against the excessive use of extensive resources for this class of patients, decisions in the ED should be largely unbiased and based on the appropriate factors relevant to the individual case. As with all patients with clinical indications for invasive monitoring or interventions, decisions should be based on factors including the patient’s wishes (if known) or a surrogate’s assessment of the patient’s wishes, expected outcome of the intervention, and potential risks of the intervention. Interventions should not be withheld or discontinued merely because of the presence of AIDS.

If certain diagnostic and therapeutic interventions are withheld, particular attention should be made to ensure adequate control of pain and other symptoms. Psychosocial, religious, and cultural needs also should be addressed.

The courts have addressed increasing numbers and varieties of cases regarding the treatment of AIDS and HIV-related illness. The AIDS Litigation Project (a review of cases) has shown increasing cases of litigation involving areas of AIDS education, blood supply, epidemiologic surveillance, criminal law, public places, products and fraud, torts, court system, family law, confidentiality, prisons, military, fear of exposure, homelessness, and discrimination.101

In general, the same ethical principles of respect for autonomy, beneficence, nonmaleficence, justice, confidentiality, communication, informed consent, and research ethics should be honored in the treatment of HIV-infected patients as for all ED patients.

### PRECAUTIONS AND POSTEXPOSURE PROPHYLAXIS FOR HEALTH CARE WORKERS

#### Precautions and Exposures

Health care workers often are exposed to the blood and body secretions of HIV-infected patients or of other persons who are at high risk of harboring HIV and other infectious pathogens. The overall risk of having any occupational blood exposure is not insignificant, with more than one half of emergency physicians reporting at least one occupational exposure during a 2-year period.102

The overall risk of contracting HIV infection remains small. As of December 2006, the CDC had received reports of 57 documented cases of HIV seroconversion that were temporally associated with occupational exposure to HIV among U.S. health care workers.103 An additional 140 infections among health care workers were considered to represent possible cases of occupational transmission. No new documented cases of occupationally acquired HIV/AIDS have been reported since December 2001. Global surveillance data is less reliable, so the overall rates of occupational transmission are not known. A majority of cases occurred in nurses; less frequently affected were laboratory technicians and physicians.104 Of all transmissions, a majority were percutaneous, followed by mucocutaneous or both. There have been no confirmed seroconversions to date with exposures to a suture needle. Efficacy of transmission is estimated at 0.3% for percutaneous exposure and 0.09% for mucocutaneous exposure.104

The proportion of patients infected with a pathogen varies by geographic setting and practice locale. A survey conducted at a Baltimore inner city hospital found that up to 11% of patients were infected with HIV and nearly 24% were infected with HIV or hepatitis B or C.105 Numerous studies have demonstrated that a substantial number of patients in the ED have previously undiagnosed HIV infection, and HIV seroreactivity cannot be accurately predicted even with the aid of risk factor assessment. Because asymptomatic persons who are HIV antibody-positive can transmit the disease, all contacts with patients’ blood or body secretions must be considered to be potentially infectious by ED personnel.

HIV transmission by health care workers to patients appears to be extremely rare. Only seven cases have been reported to date, six of which occurred from a single dentist’s practice, and one from a patient who apparently acquired HIV during orthopedic surgery. At present, routine screening of health care personnel is not indicated.

Numerous studies have demonstrated that health care workers can significantly reduce their risk of exposure to blood-borne pathogens by following universal precautions. CDC guidelines for universal precautions include the use of protective equipment (including gloves, gown, mask, and eye protection) for any situation in which the potential for exposure exists. Protective equipment is indicated for most ED procedures, including examination of the bleeding patient, chest tube placement, lumbar puncture, and other commonly performed procedures in which contact with blood or body fluids is likely. Although significant improvement has been made in observance of universal precautions in the ED setting, studies have indicated that continued education and improvements in work environments are required to ensure consistent compliance.106,107

#### Postexposure Prophylaxis

##### Occupational Exposures

Postexposure prophylaxis (PEP) reduces the risk of HIV transmission and seroconversion.108 The CDC provides explicit guidelines for institution of PEP for occupational exposure to HIV.104 Current guidelines advise case-by-case determination of exposure risk to resolve whether PEP should be recommended. Recommendations are based on two primary factors: (1) type of exposure and (2) HIV status of the source (or, if the source status is unknown, evaluation of risk status of the source). Separate recommendations are provided by the CDC for percutaneous and mucous membrane or nonintact skin exposures. Exposures involving contact between intact skin and blood or other body fluids contaminated by HIV are not indications for therapy. Higher-risk percutaneous exposures associated with an increased likelihood of transmission include those involving deep injuries, visible blood on a device, and injuries sustained during placement of a catheter in a vein or artery; lower-risk percutaneous exposures are superficial or involve solid needles. High-risk sources are patients with symptomatic HIV infection, AIDS, acute seroconversion, or high viral load; low-risk sources are patients with asymptomatic HIV infection or viral load of less than 1500 copies/mL.109 When the serostatus of the source is not known (i.e., no recent positive or negative results on serologic tests), rapid testing should be performed. A negative result on EIA (using either SUDS or OraQuick) is adequate for a decision to withhold or discontinue therapy if initiated. Some states allow testing the source patient without informed consent. Confidentiality should be rigorously protected while still ensuring that the appropriate information is provided to all exposed persons. In unusual circumstances in which the source patient has an illness consistent with acute
HIV infection, testing should include assay of HIV RNA levels.

Current public health guidelines recommend a 4-week regimen of two drugs for most HIV exposures given by percutaneous or mucous membrane routes. Two-drug therapy options include zidovudine plus lamivudine (available as Combivir), lamivudine plus stavudine, and didanosine plus stavudine. For highest-risk exposures, an expanded PEP regimen with the addition of a protease inhibitor (preferably lopinavir plus ritonavir) is advised. When the source is known to be infected with a resistant HIV strain, the selection of PEP drugs to which the source’s virus is unlikely to be resistant is recommended.

PEP should be initiated as soon as possible, preferably within hours rather than days of exposure; in general, antiretroviral therapy is not indicated in patients presenting more than 36 hours after exposure. The optimal duration of PEP is 4 weeks, if tolerated. Constitutional and gastrointestinal side effects may be significant and often lead to early termination of treatment. Initial treatment should never be delayed during the wait for information regarding final determination of overall exposure risk, because therapy subsequently can be altered or stopped after the first dose. If the source person’s HIV infection status is unknown at the time of exposure, use of PEP should be decided on a case-by-case basis, with type of exposure and likelihood of HIV infection in the source taken into consideration. If the findings suggest a possibility for HIV transmission and the result of HIV testing of the source person is pending, a two-drug PEP regimen should be initiated until laboratory results become available. PEP should be discontinued if the source patient is determined to be HIV-seronegative. In addition to the evaluation and management of HIV exposure risk, all patients should be tested and treated for other highly infectious diseases, such as hepatitis.

Patients often present to the ED seeking PEP because services are available at any time and early initiation of PEP is critical for efficacy. Many EDs are developing protocols and starter treatment packets for PEP. If possible, however, the choice of intervention and regimen usually is best accomplished in consultation with an infectious disease specialist and the patient’s primary physician, to allow arrangement for appropriate medical follow-up and counseling.

Nonoccupational Exposure

Recent interest in the use of PEP for nonoccupational exposure has emerged, because the probability of HIV transmission by certain sexual or injection drug exposures is of the same order of magnitude as for percutaneous exposures, for which the CDC recommends PEP. The current DHHS recommendations regarding nonoccupational postexposure prophylaxis (nPEP) are as follows: (1) For persons seeking care at 72 hours or earlier after nonoccupational exposure to blood, genital secretions, or other potentially infectious body fluids of a person known to be HIV-infected, when that exposure represents a substantial risk for transmission, a 28-day course of a HAART regimen is recommended, and antiretroviral medications should be initiated as soon as possible after exposure. (2) For persons seeking care at 72 hours or earlier after nonoccupational exposure to blood, genital secretions, or other potentially infectious body fluids of a person of unknown HIV status, when such exposure would represent a substantial risk for transmission if the source were HIV-infected, no recommendations are made for the use of nPEP. (3) For persons with an exposure history that represents no substantial risk for HIV transmission or who seek care later than 72 hours after exposure, DHHS does not recommend the use of nPEP. (4) Clinicians may consider prescribing nPEP for exposures conferring a serious risk for transmission, even if the person seeks care later than 72 hours after exposure if, in their judgment, the diminished potential benefit of nPEP outweighs the risks for transmission and adverse events. All patients seeking care after HIV exposure should be tested for the presence of HIV antibodies at baseline and at 4 to 6 weeks, 3 months, and 6 months after exposure to determine whether HIV infection has occurred. In addition, testing for STDs, hepatitis B and C, and pregnancy should be offered. Early experience with implementation of these guidelines indicates that challenges exist in ensuring routine implementation.

For most cases in which a patient with recent exposure is likely to have continuing risk for exposure, the CDC recommends providing basic risk reduction counseling and referral to risk reduction programs rather than offering PEP. Additional resources should be used whenever possible to assist with decision making and follow-up services; in-house infectious disease consultation should be sought. Other useful resources for information on both occupational and nonoccupational exposure include the CDC/University of California–San Francisco (UCSF) National Clinicians PEP Hotline (1-888-448-4911), providing 24-hour assistance, and the University of California at Los Angeles (UCLA)’s online decision-making support (http://www.needlestick.mednet.ucla.edu).

KEY CONCEPTS

- The seroprevalence of HIV infection and AIDS among patients presenting to EDs serving large metropolitan areas is 2 to 15%. Many of these are undiagnosed cases, so compliance of ED personnel with universal precautions is extremely important.
- Acute HIV seroconversion syndrome commonly follows exposure by 2 to 6 weeks and manifests with common nonspecific signs and symptoms such as fever, fatigue, diarrhea, weight loss, adenopathy, and rash. Patients fitting this profile should be screened for HIV risk factors and appropriately referred for HIV testing.
- PCP is the most common opportunistic infection in patients with AIDS. It often manifests as progressive dyspnea on exertion associated with a nonproductive cough. The chest radiograph commonly shows a diffuse interstitial infiltrate but may be normal in appearance. Blood gas analysis usually reveals hypoxemia that often is more pronounced after exercise.
- CNS disease is common in HIV-infected patients and may be caused by the disease itself, opportunistic infections, or malignancy. An algorithm for the evaluation of HIV-infected patients with severe or prolonged headache, altered mentation, new-onset seizures, or focal neurologic deficits is presented in Figure 130-2.
- The evaluation and management of HIV-infected patients with acute symptoms often are complex and best accomplished either in the hospital or in the outpatient setting with close follow-up.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Parasitology has become increasingly important in the practice of emergency medicine. Recent years have seen a dramatic increase in immigration from South East Asia, Central and South America, and Africa into the United States. Many of the people in transit have left their countries of origin under dire circumstances, fleeing civil unrest, war, famine, economic hardship, political persecution, and environmental devastation; they often lived in regions where parasitic infections were endemic. Business and adventure travel, including ecotourism, frequently transports immunologically naive and vulnerable hosts to sites rich in parasitic disease (Fig. 131-1). Patients with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) who travel to countries where parasitic illnesses are endemic are at higher risk of contracting these illnesses. Patients with AIDS who emigrate or travel to the United States or Europe may harbor a number of devastating parasitic illnesses. There is a significant prevalence of endemic parasitic disease in many rural areas of the southeastern and southwestern United States and in some parts of Europe. Often, patients with parasitic illness initially seek treatment in the emergency department (ED).

Correct diagnosis and chemotherapy given early in the course of parasitic illness often result in rapid recovery (Table 131-1); mismanagement can be disastrous. Osler wrote, “Early in the course of disease, diagnosis is difficult and treatment easy; late in the course, diagnosis is easy and treatment difficult.” Parasitic illness often begins insidiously and, without appropriate treatment, commonly pursues a chronic course, eventuating in end-organ damage and severe morbidity and even death. To diagnose parasitic infection, the emergency physician will need to play detective, obtaining a thorough travel history, performing a detailed physical examination, ordering appropriate laboratory studies, and integrating these findings with a strong understanding of the basic life cycles of parasites, usual and unusual presentations of infection, and the intersecting geography of the organism and the host.

An important point is that the incubation period for the development of symptoms for parasitic diseases ranges from days (falciparum malaria) to months (vivax malaria) to years (filariasis). Uncovering parasitic illness depends heavily on Osler’s principle—to make the diagnosis, one must first think of the diagnosis.

A detailed account of individual parasites can be found in Bell’s *Tropical Medicine*1 and Guerrant and colleagues’ *Tropical Infectious Diseases*.2

**Travel History**

Parasitic illness should be considered in the differential diagnosis for almost every sign or symptom imaginable, particularly in patients who recently have spent time in areas of the world with endemic parasitic illnesses (Table 131-2). Accordingly, a travel history should be included in the evaluation of most if not all patients presenting to the ED. Important questions are summarized in Box 131-1. For patients who recently emigrated to the United States, the history should elicit additional information specific to the country of origin, also summarized in Box 131-1.

**PRINCIPLES OF THERAPY**

New and more effective antiparasitic agents are continually being developed. The list of drugs used to treat parasitic infections is large and varied (Table 131-3; see also Table 131-1). Table 131-3 includes some of the newest pharmaceutical agents, in addition to many medications that, although still recommended, have become almost obsolete because of toxicity or mediocre efficacy.

The newer antiparasitic drugs are less toxic to the patient and more effective. Parasite biochemical pathways are sufficiently different from those in the human host to permit selective interference by relatively small doses of chemotherapeutic agents. In many instances, single-dose treatment can eradicate an entire parasite burden, and this approach has led to implementation of mass treatment programs in infected populations in endemic areas. Treatment and disposition in the ED focus on the individual patient and particular disease entity. The evolutionary goal of the successful parasite is to live with and at the expense of the living host; a parasite that kills its host has no survival advantage. Most parasitic infections (with certain important exceptions, such as falciparum malaria) pursue a chronic course and are not acutely life-threatening. Alterations in host immune function can change the virulence and morbid course of more benign infections (e.g., strongyloidiasis can become fulminantly disseminated in patients receiving immunosuppressive medication after organ transplantation or after the initiation of long-term steroid therapy). Despite the subacute or chronic nature of most parasitic infections,
when a diagnosis (or a diagnostic plan) has been made and chemotherapy instituted, arrangements for careful follow-up and repeat laboratory examinations will be needed to ensure a cure. When the parasites are not eliminated promptly, repeat doses or alternative drugs should be considered, because drug resistance is becoming increasingly common. In such cases, referral to a geographic medicine clinic or an infectious disease clinic is indicated. Any patient who appears clinically ill or has presumptive falciparum malaria (by symptoms or travel history) should be admitted to the hospital for initial diagnosis, treatment, and observation.

## FEVER

### Malaria

**Principles of Disease.** The febrile patient with shaking chills and a time-appropriate history of travel to an endemic region should be evaluated for malaria. *Plasmodium falciparum, Plasmodium ovale, Plasmodium vivax,* and *Plasmodium malariae* are the species responsible for human malaria. More than 41% of the world’s population lives in malaria-endemic areas (e.g., parts of Africa, Asia, Oceania, Central America, and South America). Approximately 300 million to 500 million clinical infections occur annually, resulting in 1.5 million to 2.7 million deaths.\(^3\) Approximately 1500 cases of malaria are diagnosed yearly in the United States. The female *Anopheles* mosquito is the arthropod vector that can transmit malaria after ingesting gametocytes from infected persons. After sexual reproduction in the gut of the mosquito, sporozoites are released from the salivary glands of the arthropod into the human host during a blood meal. Sporozoites rapidly penetrate the liver parenchymal cells of their host. The protozoans, now termed *cryptozoites* or *exoerythrocytic schizonts,* rapidly multiply. Eventual lysis of the hepatic cells results in the release of merozoites into the bloodstream, where they invade erythrocytes. In *P. vivax* and *P. ovale* infection, dormant hypnozoites can reside in hepatocytes; recrudescence of infections can occur many months to years later.

After invading red blood cells (RBCs), the merozoites transform into trophozoites, which feed on the cells’ hemoglobin.

Questions for All Patients
- What were the exact dates of travel?
- What countries did the patient visit?
- How much time was spent in each country?
- What was the patient doing in the country, and where was he or she living?
- Was the patient a tourist, an adventure traveler, or a worker?
- Did the patient stay in cities or rural villages?
- Was the patient sleeping in hotels or tents?
- Did the patient engage in protected or unprotected sexual intercourse?
- What did the patient eat and drink?
- What were the patient’s activities (e.g., swimming in freshwater leads to schistosomiasis)?
- Did the patient receive prophylactic immunizations before travel?
- Did the patient take malaria chemoprophylaxis and comply with the regimen?
- Did the patient use mosquito repellent and netting?
- Does the patient have underlying chronic medical problems?
- What medications does the patient take?
- When did symptoms start, and what has been the chronology of symptoms, particularly fever and diarrhea?

Questions for Patients Who Are Recent Immigrants to the United States
- When did the patient arrive and from where?
- What acute and chronic illnesses did the patient have previously while living in the country of origin?
- What treatment did the patient receive there?
- If a refugee, what countries did the patient pass through, and what were the living conditions (especially relevant for persons who have lived in numerous refugee camps)?
- What was the season during the patient’s stay or travel in the countries (e.g., monsoon versus dry)?
- What animal exposures and bites has the patient experienced?
- Has the patient had exposure to fresh water, in either work or recreational activities?

*aSome drugs available from CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, 30333, telephone: 404-639-3670 (nights, weekends, and holidays: 404-639-2888).

Trophozoites mature into schizonts, which may divide asexually into additional merozoites. The RBCs undergo lysis, releasing merozoites into the blood. Although some merozoites are destroyed by the host’s immune apparatus, many enter new erythrocytes. After several repetitions of this erythrocytic cycle, the cyclic process changes, and male microgametocytes or female macrogametocytes may develop instead of merozoites. These gametes subsequently complete the reproductive cycle by fusion, accomplished sexually, within the gut of a new female Anopheles mosquito after she has taken a blood meal from an infected host. Most people contract malaria after being bitten by an infected vector mosquito in an endemic region. Other means of transmission have been reported, including blood transfusions, injection drug use with contaminated syringes, perinatal transmission, organ transplantation, and so-called airport malaria. Airport malaria has been reported in people who have never been in an endemic area but live near or work in an international airport. The infected mosquito is transported from the endemic region and released when the plane arrives at its destination.

Clinical Features. Most patients with malaria present with irregular fevers. Other signs and symptoms include anemia, headache, nausea, chills, lethargy, abdominal pain, and upper respiratory complaints. The important difference between P. falciparum and the other malaria species is the capacity of P. falciparum to cause severe organ system damage and death. Acute falciparum infection may have any of the following manifestations: cerebral malaria with cerebral edema and encephalopathy (Fig. 131-2), hypoglycemia (especially in children), metabolic acidosis, severe anemia, renal failure, pulmonary edema, disseminated intravascular coagulation, and death.

In chronic malaria, hepatosplenomegaly may develop because of increased cellularity from the host’s immune response. Within the liver, parasites and malarial pigment distend the Kupffer cells. Parasitized RBCs also adhere to the sinusoidal system of the spleen, reducing its immunologic effectiveness. Anemia results from acute and chronic hemolysis. So-called blackwater fever—hemoglobinuria caused by severe hemolysis—may occur in patients with either chronic or acute falciparum malaria.

Diagnostic Strategies. Light microscopic examination of thick and thin blood films is the “gold standard” modality for the diagnosis of malaria. The clinician may have to view several slides to make the diagnosis if the parasite burden is small. Peripheral blood smears are stained with Giemsa or Wright stains and examined with ordinary light microscopy. The diag-
Diagnosis can be made in a simply equipped laboratory. Even if the parasite is not visualized in the smear, treatment for malaria is nevertheless indicated if the disease is suspected on clinical grounds. The U.S. Food and Drug Administration (FDA) has approved the use of an antigen-based rapid diagnostic test for screening patients. Microscopy must still be performed in all patients with positive results on such tests, to determine species and the severity of parasitemia.

**Management.** In the past, chloroquine phosphate was the treatment of choice for acute, uncomplicated attacks of malaria. Resistance to chloroquine has been steadily increasing, and now the drug should be used only in regions of known chloroquine sensitivity: Haiti, Dominican Republic, Central America, and limited regions of the Middle East. For uncomplicated malarial infections in patients from chloroquine-resistant regions, oral quinine and doxycycline given together may be used. Another suitable alternative combination is proguanil-atovaquone. For complicated 
*P. falciparum* infection (e.g., cerebral malaria, involvement of multiple organ systems, unability to tolerate oral medication), intravenous quinine (not available in intravenous form in the United States) or quinidine is used. Rapid infusion of intravenous quinine can cause profound hypoglycemia. Patients should not receive intravenous quinine without cardiac monitoring.

The artemisinin agents are excellent antimalarials and are available in enteral and parenteral preparations. They have a rapid onset of action and are well tolerated. Most are not available in the United States; however, artesunate (which is an artemisinin agent) is now available as an investigational new drug for patients who have complicated malaria not responding to quinidine. To obtain this drug, physicians can contact the Centers for Disease Control and Prevention (CDC) Malaria Hotline at 770-488-7788 or, during off hours, at 770-448-7100.7

**Babesiosis**

Babesiosis is a malaria-like illness that is becoming increasingly prevalent in the northeastern United States (*Babesia microti*), the northwestern United States (*Babesia gibsoni*), and Europe (*Babesia divergens*). Babesiosis is endemic on Martha’s Vineyard and Nantucket. The organism is a protozoan similar in structure and life cycle to the plasmodia. It is transmitted by the deer tick, *Ixodes dammini*, the vector of Lyme disease. Several cases have been attributed to transfusions with infected blood.10 Patients with babesiosis experience fatigue, anorexia, malaise, and emotional lability, with myalgia, chills, high spiking fevers, sweats, headache, and dark urine. Other manifestations include hepatosplenomegaly, anemia, thrombocytopenia, leukopenia, elevated liver enzyme levels, and signs of hemolysis with hyperbilirubinemia and decreased haptoglobin. In an otherwise healthy person, the disease may remit spontaneously. In asplenic, elderly, and immunocompromised patients (especially patients with AIDS and patients taking corticosteroids), 85% of RBCs may contain organisms. Clinical syndromes include massive hemolysis, jaundice, renal failure, disseminated intravascular coagulation, hypotension, and adult respiratory distress syndrome.11 Diagnosis is based on clinical suspicion, multiple thin and thick blood smears, and serologic testing (results of which may not turn positive for several weeks after the infection). The treatment of choice consists of quinine plus clindamycin. Patients infected with *B. divergens* tend to be sicker and require more supportive care. Co-infection with *Borrelia burgdorferi*, the agent of Lyme disease, results in more severe and prolonged illness.12 *Babesia* organisms resemble plasmodia in blood smears.
Other Parasites Causing Fever

Other parasitic illnesses that commonly cause significant fever include schistosomiasis, fascioliasis, African and American trypanosomiasis, leishmaniasis, toxoplasmosis, and amebic liver abscess. Katayama fever may be the initial phase of schistosomiasis. Infected patients report brief exposures to fresh water in endemic areas. Clinical manifestations include spiking fevers, diaphoresis, and cough. Eosinophilia is common.\textsuperscript{13} Fascioliasis, caused by the liver fluke, \textit{Fasciola hepatica}, is endemic throughout Asia, the former Soviet Union, southern Europe, and South America. Infection begins with ingestion of the metacercariae often found in watercress. Within 6 weeks, patients exhibit right upper quadrant abdominal pain, fever, and eosinophilia.\textsuperscript{14}

American trypanosomiasis (Chagas’ disease) is endemic to Central and South America. The vector, the reduviid bug, sheds trypomastigotes in its feces proximal to the bite site, leading to local infection and subsequent systemic spread in the host. Acute Chagas’ disease begins with the chagoma, the infected and swollen bite site often periorbital in location, and quickly progresses to fever, malaise, facial swelling, and pedal edema. Parasitization of cardiac muscle leads to the dysrhythmias and ventricular dysfunction that are classically found in late disease (chronic Chagas’ cardiopathy).\textsuperscript{15} Leishmaniasis is spread to humans by the sandfly and is found in the Middle East, India, and East Africa; along the Mediterranean coast; and in Brazil. Although leishmaniasis can involve the skin (cutaneous) and the mucosa (mucosal), fever is seen only in visceral leishmaniasis in immunocompetent persons. Signs and symptoms also include massive hepatosplenomegaly, neuropenia, and weight loss.\textsuperscript{16} Amebic liver abscesses frequently manifest with high fever, right upper quadrant pain, and an elevated white blood cell count.\textsuperscript{17}

\section*{NEUROLOGIC SYMPTOMS}

Cerebral Malaria

\textbf{Principles of Disease and Clinical Features}. Cerebral malaria is a common, life-threatening complication of \textit{P. falciparum} infection. Parasitized RBCs express malarial cell surface glycoproteins called knobs that are sticky. They adhere to capillary walls, causing sludging in the cerebral microvasculature, localized ischemia, capillary leak, and petechial hemorrhages. Clinical manifestations include fever, altered mentation including obtundation and coma (see Fig. 131-2), and occasionally seizures. A careful history and early diagnosis and therapy are essential to prevent severe morbidity and death.

\textbf{Management}. Treatment of cerebral malaria consists of intravenous quinine, quindine, or artemisinin (if available); supportive care, including mechanical ventilation for comatose patients and patients with noncardiogenic pulmonary edema; antiepileptics; and correction of acidosis and hypoglycemia (associated with quinine use and cerebral malaria). The mortality rate is high, especially in children (30%), but if the patient recovers, neurologic sequelae are rare (seen in less than 10%).\textsuperscript{18,19} Corticosteroids, including dexamethasone, are not beneficial and are potentially harmful in cerebral malaria.

Cysticercosis

\textbf{Principles of Disease}. Cysticercosis is caused by the larval form of \textit{Taenia solium}, a common central nervous system (CNS) pathogen in many tropical areas. It is acquired by humans who eat pork containing the larval cysts. The adult worm matures in the small intestine; the larval forms may penetrate through the gut wall and end up anywhere in the body. The most common sites include the CNS, muscle, and soft tissue.\textsuperscript{20,21}

\textbf{Clinical Features}. In the brain, the cluster of larvae of \textit{T. solium} form an expanding cyst that induces an intense immunologic reaction from the host, including inflammation, fibrosis, and ultimately calcification. Neurologic abnormalities develop when the involved neural tissue cannot accommodate the enlarging cyst. Seizure activity often is the first indication of cysticercosis, which should be considered in any adult patient with undiagnosed seizures. The diagnosis of \textit{T. solium} infection is established by finding characteristic proglottids (gravid segments) or scoleces (worm heads) in stool preparations.

\textbf{Diagnostic Strategies and Management}. Cranial computed tomography (CT) scan with contrast or magnetic resonance imaging (MRI) may reveal an enhancing ring lesion. These lesions can mimic a CNS abscess, metastasis, or a primary tumor such as glioblastoma multiforme. Albendazole is the therapeutic agent of choice, and corticosteroids may be necessary during therapy, particularly if CNS cysts are present.\textsuperscript{22} Neurosurgical consultation should be sought in treating neurocysticercosis because acute obstructive hydrocephalus can occur.

\section*{Echinococcosis}

\textbf{Principles of Disease and Clinical Features}. \textit{Echinococcus granulosus} is another tapeworm capable of causing CNS disease. Cerebral hydatid cysts are localized structures containing \textit{E. granulosus} scoleces (heads) and remains of germinal epithelium, termed hydatid sand. Common types of exposure include ingestion of food or water contaminated by the ova from feces of sheep or cattle infected by the adult worm or close contact with a sheepherding dog. Infection results in the liberation of the embryo oncosphere into the small intestine. After penetrating the intestinal wall, the larvae travel through the bloodstream to multiple sites for encystment. The liver is the target organ in nearly two thirds of cases, but 7% of patients have brain involvement; infected patients may present with seizures or focal neurologic signs.

\textbf{Diagnostic Strategies and Management}. The diagnosis of hydatid cyst disease is suggested by the appearance and localization of the cyst on ultrasound or CT scan. Serologic evaluation of serum or cerebrospinal fluid (CSF) may help confirm the diagnosis. Aspiration of the cyst should not be attempted because of the risk of seeding the host’s body with metastatic cysts. Treatment options include albendazole and surgical resection. Resection of the cyst may cause an anaphylactoid reaction if there is spillage of hydatid sand\textsuperscript{23} (Figs. 131-3 and 131-4).
Chapter 131  Parasitic Infections

1761

this intestinal parasite. Infestation occurs with ingestion of food or drink contaminated with cysts of this protozoan. Spread of amebae to the brain or meninges from the colonized large bowel wall is rare but should be considered in any patient with amebiasis and subsequent neurologic impairment. The diagnosis may be made by microscopic identification of trophozoites (motile amebae) in CSF; however, biopsy of affected tissue is more specific. CNS amebiasis is treated with intravenous metronidazole but may require neurosurgical intervention.

Naegleria and Acanthamoeba are free-living amebae in fresh water that can be acquired while swimming and diving in ponds and lakes. The amebae invade the CNS through the olfactory neuroepithelium or cornea (violated by abrasion or associated with contact lens wear), causing an amebic meningoencephalitis. The combination of amphotericin B and miconazole is the pharmacologic regimen of choice when these motile amebae are identified in CSF. Strongyloides stercoralis infection is a common disease in the tropics. The worm enters through the skin and migrates to the small bowel. Infection with Strongyloides is more clinically significant in an immunosuppressed patient, who may suffer larval dissemination throughout the body with subsequent encephalitis and pyogenic meningitis in the CNS. Strongyloides infection is treated with thiabendazole or albendazole.  

Granulomas may occur in the brain from egg deposition by Schistosoma. Generally, they do not cause major symptoms; however, several cases of transverse myelitis with paraplegia have been reported.

■ ANEMIA

Malaria

Malaria infection often is associated with anemia, especially in children younger than 5 years of age (Fig. 131-5). Anemia may develop quickly, from massive hemolysis in acute infection, or it may have a more insidious onset, developing over months. Mature merozoites lyse parasitized RBCs. Uninfected RBCs
undergo immune destruction from cell surface antibodies produced in response to parasite-associated changes in RBC surface proteins. This process of destruction is abetted by increased reticuloendothelial activity. The reticulocyte response in infected persons is blunted by inhibition of erythropoietin secretion.31,32 The antimalarial drug primaquine can precipitate hemolysis in patients who have glucose-6-phosphate dehydrogenase deficiency, which is common in black Africans and some Asians.

**Whipworm and Hookworm**

Infestation by the whipworm *Trichuris trichiura* and, especially, the two human hookworms *Necator americanus* and *Ancylostoma duodenale* is a major cause of iron deficiency anemia worldwide. Adult worms penetrate into intestinal mucosa and feed, causing significant ongoing luminal blood loss. The host defecates eggs that mature in the soil through a rhabditiform larval form to the infective filariform larva. These larvae penetrate the human skin, usually through the feet. In trichuriasis, anemia is seen only with massive parasite infestation. Ova from the whipworm are ingested through stool-contaminated food and water. Diagnosis of these infections requires identification of characteristic ova in the stool. As with most helminthic infections, peripheral eosinophilia is common. Mebendazole or a characteristic ova in the stool. These larvae penetrate the human skin, usually through the feet. In trichuriasis, anemia is seen only with massive parasite infestation. Ova from the whipworm are ingested through stool-contaminated food and water. Diagnosis of these infections requires identification of characteristic ova in the stool. As with most helminthic infections, peripheral eosinophilia is common. Mebendazole or albendazole effectively controls trichuriasis and hookworm infections in adults and children. Anemic patients should receive iron supplementation.

**Tapeworm**

Infection with the fish tapeworm *Diphyllobothrium latum* is associated with pernicious anemia. This tapeworm competes with the human host for absorption of vitamin B12. When the host ingests raw freshwater fish that contains the embryo plecercoid larvae in its muscle fibers, the adult tapeworm develops within the human small intestine. The diagnosis is made by identifying the ova in the feces. Praziquantel is the drug of choice in adults and children.

**PERIPHERAL EDEMA**

**Elephantiasis**

*Principles of Disease.* Elephantiasis, or filariasis, is manifested in the host by the development of massive peripheral edema with distention and thickening of the overlying skin, which acquires the appearance and texture of elephant skin. It is caused by infection with the filarial worm *Wuchereria bancrofti* or *Brugia malayi*. The infection is confined to humans and is widely distributed in the equatorial regions of the world, including Africa, Asia, South America, and Oceania. More than 90% of all infections are found in Asia, where the disease has reached epidemic proportions. Even in endemic regions in which most residents are infected, the disease is rare among travelers. Infected mosquitoes introduce microfilariae into the bloodstream of the human host during a blood meal. After infecting the host, the worms migrate into the lymphatic system and mature into coiled, gravid adults. The adult worm triggers a robust inflammatory reaction in the lymphatic vessels, particularly in the lower extremities and genitalia. The macrophages, lymphocytes, plasma cells, giant cells, and eosinophils migrate to the inflamed and fibrotic lymphatic vessel, which becomes erythematous, edematous, and tender, suggesting the diagnosis of filariasis.

*Clinical Features.* Chronic manifestations of filariasis include fibrosis of a lymphatic vessel containing a dead or calcified worm. Subsequent mechanical blockage of the lymphatic system leads inevitably to severe lower extremity and genital edema accompanied by thickening of the skin. Recurrent cellulitis is common in these patients; prevention requires meticulous skin care.33

*Diagnostic Strategies and Management.* The adult female worm produces microfilariae, which reach the peripheral blood through the lymphatics, whereupon the patient experiences shaking chills and fever. Thick peripheral blood smears may show infection, particularly at night, when the release of microfilariae is most likely. Diethylcarbamazine rapidly clears the microfilariae from the peripheral blood and slowly sterilizes the gravid female nematode. Established elephantiasis of the scrotum can be successfully treated surgically. Chronic lympathic obstruction of the limbs rarely responds to operative intervention.34

**DERMATOLOGIC SYMPTOMS**

**Cutaneous Leishmaniasis**

*Principles of Disease.* Cutaneous leishmaniasis is one of the most important causes of painless chronic ulcerating skin lesions in the world. *Leishmania braziliensis* and *Leishmania mexicana* responsible for New World leishmaniasis, whereas *Leishmania tropica* and *Leishmania major* commonly cause Old World leishmaniasis. The female *Phlebotomus* sandfly transmits the promastigotes during a blood meal, which are ingested by host macrophages and survive in their leishmanial form in the skin.

*Clinical Features.* Skin papules and nodules are seen early in the course of infection at the site of the insect bite. A raised macule also can appear, which subsequently develops painless central ulceration and a raised border. Lymphocyte and macrophage invasions of the epidermis and dermis cause the induration that occurs at the ulcer border. Secondary bacterial infections of these ulcers increase the associated scarring. *L. braziliensis braziliensis* (subspecies of *L. braziliensis*) attacks the mucocutaneous skin borders (i.e., in tissues of the nose and mouth). Mutilation of the face occurs after massive tissue and nasal cartilage destruction. The larynx and trachea also can be involved, compromising the airway. Disseminated cutaneous leishmaniasis (*L. mexicana amazonensis* in South America and *L. tropica aethiopica* in Ethiopia) is characterized by diffuse nodules and papules resembling those of lepromatous leprosy (Fig. 131-6). Persons with this manifestation of leishmaniasis are thought to have a defect in their cell-mediated immunity response.35,36

Figure 131-6. Cutaneous leishmaniasis.
**Diagnostic Strategies and Management.** Definitive diagnosis of leishmaniasis is made by direct visualization of the parasite with light microscopy. Diagnosis also can be made by an indirect fluorescent antibody test. Results of intradermal skin testing often are negative during the acute stages of the disease. Many forms of cutaneous leishmaniasis, especially *L. tropica* and *L. mexicana* infection, are self-limited and require no treatment, unless the wounds become secondarily infected. Treatment options for advanced disease include sodium stibogluconate, meglumine antimoniate, and amphotericin B. An oral drug, miltefosine, has been used with success for treating both the visceral and the cutaneous forms of leishmaniasis. These treatments rarely are initiated in the ED setting.

**Dracunculiasis**

**Principles of Disease and Clinical Features.** *Dracunculus medinensis,* the “fiery serpent,” appears in the host as the adult worm migrates through the subcutaneous tissues of the leg. The head of the gravid adult female erodes through the skin of the leg and releases larvae into the water when the host wades in a pond or open well. The larvae promptly infect the Cyclops water flea. Humans who drink water containing the infected crustacean complete the cycle of infection. The patient may complain of rash, intense pruritus, nausea, vomiting, dyspnea, and diarrhea before the female worm erupts through the skin.

**Management.** The “classic” treatment in developing countries has been to wind the worm around a stick and slowly extract the parasite from the skin over the course of 1 or 2 days. If the worm breaks while being extracted, the patient experiences an intense inflammatory reaction with cellulitis along the worm tract. The diagnosis is confirmed when microscopic larvae are found in the fluid of the cutaneous ulcer or when the adult female worm is identified extruding from the skin. The use of metronidazole to shorten the time of extraction is controversial. The World Health Organization set a goal to eradicate this disease through public health awareness: encouraging covering wells, filtering well water to remove the fleas, and keeping infected persons with active skin lesions out of potable water. These efforts have had a tremendous impact on the eradication of dracunculiasis from Africa.

**Other Parasites Causing Dermatologic Symptoms**

Cutaneous larva migrans, the “creeping eruption,” occurs in the host’s epidermis when the skin is penetrated by *Ancylostoma braziliense* (dog or cat hookworm) larvae. Exposure usually occurs after walking barefoot or lying on beaches or other warm soil contaminated by animal feces. The diagnosis is suggested by the presence of a characteristic meandering erythematous track on the skin surface caused by larval migration. Visceral larva migrans occurs in young children after ingestion of soil containing ova from the dog ascarid *Toxocara canis.* Thiabendazole, ivermectin, or albendazole may be used for treatment of cutaneous larva migrans, and antipruritics give symptomatic relief. Diethylcarbamazine treats visceral larva migrans. An alternative is thiabendazole.

“Swimmer’s itch” is a dermatitis that occurs when skin is penetrated by the nonhuman schistosome of avians and mammals, usually from swimming in northern U.S. freshwater lakes. The infection spontaneously resolves when the nonhuman schistosome is destroyed by the host’s immune system. A similar dermatitis also can occur after infection with schistosome species that are trophic for humans. Treatment is symptomatic.

**Strongyloides** can cause a transient, pruritic rash that may appear and then disappear within hours. *Taenia solium* can cause cysts in the soft tissues and muscles. These cysts often are an incidental finding. Onchocerciasis (from *Onchocerca volvulus*), which is commonplace in West Africa and parts of South America, can cause severe pruritus and the development of nodules on bony protuberances.

**VISUAL SYMPTOMS**

**Onchocerciasis**

**Principles of Disease.** Onchocerciasis is a major cause of blindness in the world. Ninety-five percent of all cases occur in Africa. The parasite is found only in humans and is transmitted by the bite of the *Simulium* fly. These flies live near rivers—hence the common name of the disease, “river blindness.” Microfilariae of *O. volvulus* are released by adult nematodes, which coil in subcutaneous nodules in the infected host; the microfilariae then migrate through the dermis and epidermis. The presence of adult worms stimulates a brisk immune response, including the infiltration of lymphocytes, macrophages, plasma cells, and eosinophils.

**Clinical Features.** The skin becomes chronically edematous and pruritic; it then atrophies, resulting in loose, thin folds of skin. River blindness is more likely to develop in patients with nodules in proximity to the eyes. When the microfilaria dies during its migration in the eye, the foreign tissue that is deposited in the iris musculature incites an immune-sclerosing keratitis, which is a major cause of the ocular destruction with subsequent blindness (Fig. 131-7).

**Diagnostic Strategies and Management.** The diagnosis of onchocerciasis requires identification of characteristic microfilariae in skin snipped from the patient. Ivermectin is the therapeutic drug of choice. In many countries in which the disease is endemic, the manufacturers of ivermectin have donated the drug in an attempt to eradicate the disease. Surgical excision of the subcutaneous nodules is recommended when they are located on the head.

**Loiasis**

**Principles of Disease and Clinical Features.** Another filarial infection that causes ocular problems is loiasis. Loiasis is confined to forest areas in West and Central Africa. Transmission of *Loa loa* occurs through the bite of flies of the genus *Chrysops.* The edema initially associated with migration of the worm is called a *Calabar swelling.* The disease is caused by a migrating adult worm in the subcutaneous tissue. The adult worm occasionally

Figure 131-7. Patient with onchocerciasis, or “river blindness.”
migrates through the subconjunctival tissues of the eye and can be surgically excised from the conjunctiva. Although upsetting to the patient, the disease often is fairly benign. The adult worm releases sheathed microfilarial larvae into the peripheral bloodstream during the daytime.

**Diagnostic Strategies and Management.** Microfilariae can be detected within a thick blood smear, securing the diagnosis of loiasis. The treatment of choice for L. loa infection is diethylcarbamazine. Corticosteroids or antihistamines often must supplement specific chemotherapy because of the intense allergic reaction that occurs when the killed adult worms and microfilariae disintegrate.40,44

**Other Parasites Causing Ocular Symptoms**

*Trypanosoma cruzi* has a tropism for the host’s eyes. Toxocariasis is a roundworm infection found in urban dogs. Humans ingest eggs by the fecal-oral route. The larvae migrate and often enter the retina, where they become trapped. They stimulate an immune response that culminates in granuloma formation. These granulomas can impair vision and sometimes are mistaken for retinal tumors. There is no means of direct diagnosis except tissue biopsy. Although serologic tests are available, results need to be interpreted with caution. Infection is treated with albendazole and steroids; larvae visible in the retina can be destroyed with a laser.

*Toxoplasma gondii* infection can precipitate a vitreal inflammation with retinal hemorrhages. Immunocompromised patients may develop chorioretinitis and optic neuritis with visual field defects and ocular palsies. Erythrocytes with sticky “knobs” from *F. hepatica* infection can cause retinal vascular congestion and ischemia with hemorrhage, exudate, infarction, and macular destruction. Cerebral malaria can produce cortical congestion and ischemia with hemorrhage, exudate, infarction, “knobs” from *E. histolytica* infection may result in obstructive or restrictive lung disease. Microfilariae can be seen in lung biopsy material. Untreated infection may result in obstructive or restrictive lung disease. Patients have marked eosinophilia and elevations of serum IgE.48

*Paragonimus westermani* and echinococcal species are trophic for the lungs in their human hosts. *P. westermani* eggs are shed in stool, hatch in fresh water, and, as miracidia, infect a snail intermediary. After further development, cercariae are released from the snail, penetrating and encysting in freshwater crab or crayfish. After consumption by the human host, metacercariae from the crab or crayfish excyst within the duodenum, penetrating the duodenal wall into the abdominal cavity. The larvae migrate from the peritoneal cavity through the diaphragm into the pleural cavity, finally migrating to the lungs, where they cause hemorrhage, necrosis, and a granulomatous response. Early in the process, patients may have infiltrates and eosinophilia; later disease is marked by bronchiectasis, chronic bronchitis, fever, hemoptysis, and cachexia. Pulmonary nodules and cysts may cavitate.49 Many of these patients may have a positive result on purified protein derivative (PPD) testing, and their symptoms and chest radiographic findings may mimic those in tuberculosis. Sputum often is blood-streaked and flecked with dark brown particles containing diagnostic ova. Radiography, stool examination, and immune testing of sputum and blood can help make the diagnosis.50 Praziquantel is the therapeutic agent of choice.

*E. granulosus* causes pulmonary hydatid cyst disease that remains asymptomatic until a cyst grows large enough to cause a mass effect, becomes superinfected, or leaks cyst material, which is highly immunogenic, causing a severe anaphylactoid reaction. Pulmonary hydatid cysts also can be associated with cough, expectoration of sputum, chest pain, and hemoptysis.51 Primary hydatid disease in the liver can metastasize to the lungs or brain. A thoracic CT scan shows a unicellular lung cyst; on a plain radiograph, a ruptured cyst is said to resemble a water lily—a pathognomonic finding. Cysts can be treated with careful surgical excision and pharmacotherapy.

Early schistosomal disease, or Katayama fever, can manifest with fever, cough, eosinophilia, and diffuse pulmonary nodules as the schistosomula pass through the lungs. In long-standing disease, ova shed from worm pairs can lodge in the vasculature of the lungs, causing pseudotubercles, granulomatous lung disease, pulmonary hypertension, and cor pulmonale. In
patients with long-standing, latent, and asymptomatic *S. stercoralis* infections who are started on corticosteroids or immunosuppressive therapy, the helminth disseminates widely. Fatal, massive pulmonary infections with radiographic white-outs and unsupportable respiratory failure have been reported in patients who have received organ transplants; this clinical disaster occurs more commonly in patients who originally came from developing countries and were never evaluated for *Strongyloides* infection before transplantation.52,53 *Strongyloides* infection can be misdiagnosed as bronchospasm and asthma, prompting the clinician to prescribe steroids, which precipitate infection.54

---

**CARDIOVASCULAR SYMPTOMS**

**Chagas’ Disease**

*Principles of Disease.* *T. cruzi* infection causes acute and chronic myocarditis. *T. cruzi* is endemic in South and Central America and causes Chagas’ disease. The vector is the reduviid or “kissing bug” that inhabits the walls and roofs of thatched dwellings built adjacent to forest. Previously a disease of rural populations, urban transmigration has expanded the epidemiologic scope of Chagas’ disease. The disease is not seen commonly in travelers. The reduviid’s bite is no longer the only source of *T. cruzi* infection; transfusion with blood containing live trypanosomes from infected hosts is a growing source of infection.55 Oral transmission also has recently been noted as well.56

The reduviid bites the patient, often around the eye, and excretes feces containing the trypomastigote of *T. cruzi*. The trypanosome enters the inflamed bite wound or other mucosal or conjunctival surfaces, causing a local swelling, called a *chagoma*. Romana’s sign (painless unilateral periorbital edema) is pathognomonic but rarely seen. The trypomastigote migrates to trophic tissues, including smooth muscle, cardiac muscle, and autonomic ganglia in the heart, esophagus, and colon, causing local inflammation and tissue destruction.

*Clinical Features.* Acute infection is heralded by fever, facial and dependent extremity edema, hepatosplenomegaly, lymphadenopathy, malaise, lymphocytosis on peripheral blood smear, and elevated liver transaminases. At this stage, fatal left ventricular dysfunction and dysrhythmias are uncommon. Early illness lasts 1 to 2 months and resolves spontaneously, resulting in a latency known as the *indeterminate phase*, which can persist throughout the patient’s lifetime. In approximately 25% of the cases, the infection progresses to chronic Chagas’ disease, principally with cardiopathy and gastrointestinal disease. Amastigotes invade cardiac muscle and the cardiac conduction system. Chronic inflammation, mononuclear cell infiltration, and fibrosis are other findings. Additional features may include atrial bradydysrhythmias, right and left bundle branch blocks, complete heart block, and ventricular dysrhythmias including ventricular fibrillation. With development of right and left ventricular dysfunction with dilated cardiomyopathy, cardiac muscle is replaced by fibrosis and scarring. Mural thrombi are common; thromboembolic disease manifesting as pulmonary embolism, stroke, or peripheral arterial embolism can be the first indication of long-standing asymptomatic infection. Congestive heart failure is rapidly progressive and fatal within months unless aggressively treated with pharmacologic intervention and transplantation.57

*Diagnostic Strategies.* Acute Chagas’ disease can be diagnosed by the presence of motile trypomastigotes in anticoagulated blood specimens. The organism also can be cultured in special liquid media. Chronic Chagas’ disease can be diagnosed using several serologic tests, including complement fixation, enzyme-linked immunosorbent assay (ELISA), and indirect immunofluorescence testing. The assays are nonspecific, cross-reacting with malaria, syphilis, leishmaniasis, and some collagen vascular diseases. Polymerase chain reaction technology is improving and soon will provide the “gold standard” modality for diagnosis.58

*Management.* Nifurtimox and benznidazole are used for treating *T. cruzi* infection. Cure rates rarely exceed 50%. The duration of treatment with nifurtimox is prolonged, and the drug has many serious side effects. Its production has been discontinued; however, it is the only antitrypanosomal medication available in the United States today (it can be obtained from the CDC by calling 404-639-2888). Benznidazole has fewer side effects. It is now recommended for indeterminate-phase treatment. Late complications of chronic diseases are modulated by autoimmune activity and do not respond to antiparasitic pharmacotherapy. Use of nifurtimox and benznidazole has been associated with lymphoma in an animal model.59,60 Chronic Chagas’ disease of the heart, esophagus, or colon is treated symptomatically. Automated implantable cardioverter-defibrillators have been demonstrated to decrease the incidence of sudden death in this patient population.61 Patients receiving immunosuppressive therapy to prevent rejection after cardiac transplantation have shown recurrent disease in the transplanted myocardium.

*Other Causes.* Aberrant migration of *Ascaris* to the myocardium is well described, causing myocarditis and pericardial effusions. *E. histolytica* abscesses of the liver also may cause pericardial effusions if they erode through the diaphragm.

---

**GASTROINTESTINAL SYMPTOMS**

**Diarrhea**

Diarrhea is one of the most common symptoms for which travelers seek medical attention. Gorbach62 wrote, “Travel expands the mind and loosens the bowels.” Diarrhea also is the leading cause of death in children younger than 5 years of age in developing countries and a major source of morbidity for older children and adults (Fig. 131-8). Most diarrheal disease is viral or bacterial; however, some clinically significant diarrheal disease is caused by parasites. *Cryptosporidium parvum* and *Cyclospora cayetanensis* are food-borne and water-borne coccidians that cause watery diarrhea.

---

*Figure 131-8.* Fecal-oral transmission of diarrheal agents occurring in a developing country.
Both are particularly significant causes of morbidity in malnourished children and patients with AIDS. In these populations in the developing world, the prevalence may approach 50%. Cryptosporidial oocysts can be seen in stool when an acid fast–based stain is used. ELISA and immunofluorescent assays of stool also are available. Paromomycin decreases diarrhea frequency in patients with AIDS, who often have prolonged illness. Treatment is symptomatic for immunocompetent hosts. Cyclospora oocysts can be detected in stool samples using a Ziehl-Neelsen stain. Trimethoprim-sulfamethoxazole treats the infection.

E. histolytica causes an invasive or inflammatory diarrhea. Patients complain of fever, tenesmus, abdominal pain, and watery stool containing blood and mucus. Untreated disease can progress to widespread colitis and perforation of the bowel wall with peritonitis and death. Stool examination reveals mobile trophozoites containing ingested RBCs. Cysts noted on stool studies do not necessarily reflect active infection. Immune assays of stool can now differentiate between E. histolytica and nonpathogenic ameba species. Serologic tests may be useful in an infected patient from a nonendemic region but take a month for results to turn positive. Metronidazole is the drug of choice for treatment of amebiasis. Balantidium coli is the other protozoan that can cause invasive diarrhea. It has tropism for the terminal ileum, sometimes resulting in a clinical picture suggestive of appendicitis. Tetracycline and metronidazole are active against B. coli.

Giardia lamblia can cause persistent diarrhea, abdominal bloating, cramps, flatulence, and weight loss. The organism is ingested and reproduces exponentially in the small bowel. In severe infection, the entire jejunum becomes covered with organisms, and the patient has malabsorption with steatorrhea. The organisms are rarely seen in fresh stool preparations because they quickly break down and become indiscernible. Accordingly, an antigen test often is used to confirm the diagnosis. Giardia has many animal reservoirs, including the beaver. Campers who drink unfiltered, pure mountain spring water in the United States commonly contract Giardia infection. Metronidazole and tinidazole treat the disease.

S. stercoralis, Capillaria philippinensis, T. trichiura, and Schistosoma all have been associated with diarrhea. Hyperinfection or dissemination of Strongyloides can cause persistent diarrhea, weight loss, and abdominal pain. Trichuris causes diarrhea when the parasite load in the intestine is high. Schistosomiasis can cause a chronic granulomatous colitis, which may resemble inflammatory bowel disease, or an acute, bloody, febrile colitis associated with Katayama fever in the immunologically naive patient. In chronic schistosomiasis, worm pairs in patients’ mesenteric and portal venous systems lay eggs that become ensnared in the liver, causing intense local inflammation and scarring and the classic “pipestem” cirrhosis with periporal fibrosis. Clinical manifestations in these patients include portal hypertension, ascites, and esophageal varices (Figs. 131-9 and 131-10). Upper gastrointestinal bleeding is not as common as in patients with alcoholic cirrhosis; however, a high number of patients are infected with schistosomiasis in endemic regions, so variceal bleeding is an important cause of gastrointestinal hemorrhage in these populations.

Abdominal Pain

In an extensive review of a number of cases of appendicitis, parasitic infection was found to be the cause in 3%. Pathologic examination revealed enterobiasis, amebiasis, trichuriasis, and taeniasis.

A. lumbricoides can cause significant persistent or recurrent abdominal pain in adults and partial intestinal obstruction in children with significant worm loads. Antihelminthics and conservative, supportive therapy usually eliminate the problem, thereby avoiding surgical intervention. The diagnosis of ascariasis is made by identifying eggs in the stool. Patients with large worm loads may excrete adult worms, especially after therapy is started. Severe intestinal amebiasis can be complicated by colonic perforation and peritonitis.

Angiostrongylus costaricensis, a nematode known as the rat lung worm, is common in Central America. Infected children may appear clinically to have Meckel’s diverticulum or acute appendicitis. Manifestations of the infection include nausea, vomiting, fever, abdominal pain localized to the right lower quadrant, and a tender mass. Surgical exploration may uncover abscesses, obstruction, or intestinal infarction.

Anisakiasis is characterized by severe abdominal pain after ingestion of raw fish (sushi and sashimi primarily). Anisakis

Figure 131-9. Pipestem cirrhosis with extensive ascites in a patient with chronic schistosomiasis.

Figure 131-10. Extensive ascites in a child, which may be from schistosomiasis or kala-azar (leishmaniasis).
or cholangiocarcinoma.78 The liver fluke, _F. hepatica_, causes a syndrome that mimics viral hepatitis: right upper quadrant pain, fever, nausea and vomiting, jaundice, a tender enlarged liver, and elevated transaminases. Patients also have eosinophilia and urticaria. Imaging studies, including CT, show the tracts of burrowing flukes. Serologic testing establishes the diagnosis; the patient's stool may not contain eggs for several months after ingestion.73 The eggs of schistosomes become trapped in the portal venules, where they trigger an inflammatory response, leading to granulomatous liver disease, fibrosis, and cirrhosis. Hepatic granulomas also are seen in disseminated strongyloidiasis and aberrant biliary ascariasis.

_E. histolytica_ can cause hepatic abscesses. Affected patients typically do not have amebic dysentery and do not shed _Entamoeba_ in their stool, but results of serologic studies almost always are positive. Patients have fever, weight loss, anorexia, and right-sided abdominal pain, but no jaundice. Treatment is with metronidazole or tinidazole and a luminal amebicide, such as iodoquinol.76 _E. granulosus_ produces hydatid cysts of the liver that, on CT, contain septations and so-called daughter cysts. Pharmacotherapy with albendazole and careful excision remain the treatments of choice. Leaking cyst material can initiate a severe anaphylactoid reaction in the host.

Jaundice may result from hemolysis secondary to direct infection of RBCs with _Plasmodium_ or _Babesia_ or from biliary obstruction with pigmented stones. _Ascaris_ can cause biliary colic, pyogenic cholangitis, pancreatitis, or liver abscess. Dead worms can be the nidus for gallstone formation. Biliary imaging and endoscopic retrograde cholangiopancreatography will show worms in the biliary tree. Mechanical removal by endoscopy combined with anthelminthic therapy is curative.77 _Clonorchis sinensis_ and _F. hepatica_ are trophic for the biliary tree. These worms can be present without producing symptoms for years before eventually precipitating cholecystitis, cholangitis, or cholangiocarcinoma.78

**Pruritus Ani**

_Enterobius vermicularis_, or pinworm, causes pruritus ani, a syndrome of intense perianal itch occurring primarily in children. Autoinfection is common because children (and adults) scratch the pruritic anal area and then bite their nails or put their fingers in their mouth. The worm has a worldwide distribution. Diagnosis is clinical and is confirmed by finding the small adult worms wiggling about on the anal verge. Eggs are rarely seen in the stool but can be visualized using the tape test: Transparent tape touched to the perianal region collects eggs, which can be seen with light microscopy. Albendazole or mebendazole is the drug of choice.

**PARASITIC CO-INFECTIONS IN PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND AIDS**

**Perspective**

HIV infection and AIDS are prevalent in developing countries. Heterosexual and perinatal transmission are common; young children and young adults of both sexes are primarily infected. Patients presenting to the ED may be co-infected with HIV or any other infectious agent, including all of the parasites discussed in this chapter. HIV co-infection may worsen the symptoms and outcome, alter the presentation, increase the virulence, or assist the infective process.

AIDS causes abnormalities in almost every aspect of a host's immune response to infection; cell-mediated immunity (which is important in combating parasitic infection) is most affected.79 The diagnosis and response to therapy of many parasitic infections are monitored serologically. HIV infection interferes with this response, rendering many of these tests unreliable. Therapies that are extremely effective in the normal host may be ineffective in a patient with HIV infection. Pharmacologic agents may have to be given for long periods or for the patient's entire life.

**Specific Parasitic Infections**

Malaria is not an opportunistic infection in patients with AIDS; however, many patients, especially children, with recurrent malaria and anemia from hemolysis have required transfusions from blood supplies not screened for HIV and have become infected.80 Treating febrile patients for malaria in areas in which it is endemic is a common practice. Patients with AIDS have more severe allergic reactions to drugs, especially sulfonamides, that are antimalarials. In patients with AIDS, fever alone is not predictive of malaria; diagnosis should precede therapy. Patients with HIV infection are at greater risk for severe clinical manifestations of babesiosis.81

Visceral leishmaniasis is more commonly disseminated and fatal in patients with AIDS. Latent leishmanial infections may reactivate, and a prolonged febrile illness in an HIV-positive patient with a lifetime history of travel in leishmaniasis-endemic areas of the world should prompt consideration of this co-infection.82 Cutaneous infection also may become disseminated in these patients. Several clinical trials are currently examining the role of chemoprophylaxis for leishmaniasis in HIV-positive persons who live in endemic regions of the world. Chagas' disease in the indeterminate phase can be reactivated in patients infected with HIV. These patients frequently have CNS involvement with meningoencephalitis and severe myocarditis.83 Single-drug therapy may be insufficient, because benznidazole penetration into the CSF is minimal. _T. gondii_ infection is well recognized throughout the world as a common opportunistic infection of patients with AIDS, with a particular tropism for the CNS.

The coccidial organisms _Isospora belli_, _C. parvum_, and _C. cayetanensis_ all have been associated with prolonged diarrhea in patients with AIDS. These organisms cause infections that are difficult to treat and are almost impossible to eradicate in these patients. The diarrhea is extremely debilitating and can be as profuse as that seen in cholera. _E. histolytica_ has a high prevalence among homosexual men who practice unprotected anal intercourse; however, invasive amebiasis is not an opportunistic infection associated with HIV infection. Schistosomiasis enhances the pathogenesis of HIV infection and is more difficult to treat and eradicate in patients who are HIV-positive.84 _S. stercoralis_ infection is more likely to manifest as hyperinfection and disseminated disease in patients who are HIV-positive.85 In patients who are at risk for HIV infection and parasitic illness, it is essential to consider co-infection in the differential diagnosis.
# Key Concepts

- Parasitic diseases may manifest with almost any symptom or constellation of symptoms. Accordingly, a travel history should be obtained in all patients with clinically significant signs and symptoms of unclear etiology. The combination of presenting symptoms and signs and a history of recent travel to specific geographic regions can lead to early diagnosis of most parasitic infections.
- Parasitic co-infections are particularly common in patients with HIV infection and AIDS.
- Acute malaria should be suspected in patients with irregular high fever associated with headache, abdominal pain, or respiratory symptoms. Patients who are clinically ill or who are suspected of having falciparum malaria should be hospitalized for evaluation and treatment.
- Cysticercosis should be considered in the differential diagnosis for new-onset seizures.
- Giardiasis should be suspected in patients with diarrhea who recently have been camping or drinking unfiltered mountain spring water.

Tick-Borne Illnesses

Edward B. Bolgiano and Joseph Sexton

PERSPECTIVE

Ticks are hematophagous parasites of humans and animals, distributed worldwide. They transmit rickettsial, bacterial, spirochetal, viral, and protozoal diseases and cause disease by means of their own toxins (Table 132-1). As vectors of human disease, ticks rank second in importance only to mosquitoes. People who travel during the summer months may return from endemic areas with tick-borne disease. In addition, reports of infection acquired within urban areas emphasize the need to consider tick-borne illness even in the absence of a history of travel to high-risk areas.1 Tularemia (category A) and Q fever (category B) are now considered by the Centers for Disease Control and Prevention (CDC) to be significant threats during biologic warfare. For this reason, research involving ticks and their diseases has become increasingly important.

Reports on ticks, their feeding habits, and their possible relation to disease can be found from early history.2 Pliny (ce 77), in Historia naturalis, referred to “an animal living on blood with its head always fixed and swelling, being one of the animals which has no exit [anus] for its food, it bursts with over-repletion and dies from actual nourishment.” Tick-borne illness was first recognized on the North American continent by Native Americans. According to legend, Shoshone men avoided the “evil spirits” that caused illness by sending only women into certain areas of the Rocky Mountain region known to be especially hazardous. The etiologic association of the tick vector with Rocky Mountain spotted fever (RMSF) was noted by missionaries and by early settlers, who named the affliction “tick fever.” Physicians in Idaho and Montana recorded the classic clinical descriptions of the disease in 1899.

PRINCIPLES OF DISEASE

Identification of Ticks

Ticks are arthropods but not insects. They have eight legs instead of six and generally two fusing body parts—a capitulum (head) and an opisthosoma (abdomen)—instead of three. Identification of an arthropod as a tick and subsequent categorization into family and some genera are not difficult (Figs. 132-1 and 132-2). Speciation requires a trained acarologist. However, tick identification has limited importance in clinical decision-making. Color, which varies seasonally, and size, which varies by amount of blood ingested at the time of presentation, are unreliable criteria for identification purposes.

Physiology of Tick Feeding

An understanding of the physiology of feeding in arthropods is more essential than species identification in assessing the risks of transmission of diseases. Blood-sucking arthropods are divided into two groups according to their method of acquiring blood. The solenophagous feeders insert their mouthparts directly into capillaries to obtain blood. Telmaphagous feeders insert their mouthparts indiscriminately, lyse tissue along with capillaries, and feed on the resultant pool of blood, extracellular fluid, and tissue. Ticks and deer flies, for example, are telmaphagous feeders, whereas mosquitoes are mostly solenophagous.

Argasid ticks (soft-bodied), are short, rapid feeders with preformed distensible endocuticles. They therefore need to feed for only minutes to hours to acquire a full meal. As a result, they tend to be found in nests and burrows where their hosts visit frequently. The genus Ornithodoros is the vector for relapsing fever. Ixodid ticks (hard-bodied) include the genera Ixodes, Dermacentor, Amblyomma, and Rhipicephalus, which are those responsible for the remainder of human tick-borne diseases discussed in this chapter. These ticks need to form a new exocuticle (phase I of feeding) and thus feed slowly during the first 12 to 24 hours. Once fully formed, the new endocuticle allows rapid feeding (phase II) and significant engorgement.

In the capitulum of ticks, the sucking structure, consisting of the chelicerae, is surrounded by a sheath from which it protrudes during feeding. Sense organs on the capitulum, or podomeres, help locate a host by means of chemoreceptors. A special sensory structure, Haller’s organ, is located on the first set of legs and is a humidity and olfactory receptor.3 When a suitable location is found, adjacent cheliceral digits incise the skin, and the chelicerae and barbed hypostome are inserted. Two mechanisms prevent the tick from being removed from the skin: the barbed hypostome and a cement-like salivary secretion from the base of the hypostome, composed of lipopolysaccharides and glycoproteins. This allows ixodid ticks to attach for as long as 2 weeks. Because argasids are much faster feeders, they secrete no cement substance.

During a bite, trauma and salivary gland products can cause local inflammation, hyperemia, edema, hemorrhage, and skin thickening. The saliva injected during feeding contains many different substances. Both hard and soft ticks produce a histolytic secretion that liquefies tissue, which is then sucked into the gut. Eventually, the secretion breaks down the walls of the gut and the ingested blood becomes digested. The saliva also contains lytic substances capable of digesting fibrin and fibrinogen. Once engorged, ticks return to the ground or other hiding places to molt, and the acquired blood remains in the gut while the new gut lining grows to replace the old.

The Ixodes scapularis and the Dermacentor variabilis are the primary vectors of Lyme disease (category C). I. scapularis is more common in the northeastern United States and the Pacific Northwest. D. variabilis is found in the eastern and central United States. Lyme disease is more common in areas where the I. scapularis vector is most prevalent. D. variabilis is more commonly found in the southern United States, where it is less common to find Lyme disease.4

Tick-Borne Disease in North America

The distribution of arthropod-borne diseases in North America is as diverse as the geographic distribution of their vectors. In some areas, a single tick species may transmit a single disease. In other areas, several different tick species may transmit different diseases. In still other areas, several different tick species may transmit the same disease.5

Disease Transmission

Tick-borne diseases are transmitted by arthropods and usually require the blood meal of an infected host to complete their life cycle. Ticks are not vectors for all human diseases, but they are responsible for the transmission of several important diseases. The transmission of these diseases is not always easy to predict, but some factors are known to be associated with the transmission of tick-borne diseases. Ticks are most active during the spring and summer months, and they are most likely to transmit disease during these times. The presence of infected ticks in an area is also a factor in the transmission of disease. Ticks are more likely to transmit disease in areas where they are most populous. Finally, the presence of a suitable host is essential for the transmission of tick-borne diseases. Ticks are generally found in areas where people are likely to come into contact with them, such as parks, forests, and areas with brush and trees.6

Tick prevention

Tick prevention is important to reduce the risk of tick-borne disease. Several methods can be used to prevent ticks from attaching to the skin. Several brands of tick repellents are available, and these can be applied to the skin or clothing. In addition, clothing that covers the arms and legs can be worn to prevent ticks from attaching to the skin. If a tick is found on the skin, it should be removed as soon as possible. If a tick is left in place, it may transmit disease to the host.7

References

dermal blood vessels and the released blood is ingested. To prevent hemostasis, the saliva contains a thrombokinase inhibitor, apyrase, which prevents platelet aggregation by depleting adenosine diphosphate, prostaglandin E₂, and prostacyclin (prostaglandin I₂) to prevent vasoconstriction, and cytolysins. *Ixodes scapularis* also secretes a carboxypeptidase that destroys other inflammatory mediators such as anaphylatoxins and bradykinin, as well as anti–complement C3 factor. These other mediators normally would cause further inflammation, which would enhance hemostasis. All infectious agents, as well as excretory liquids from some argasids, are transmitted through this saliva. Transmission of a disease from *Ixodes* ticks is unlikely if the tick is not yet engorged with blood at the time of removal. Likewise, a tick removed within a few hours after attachment is unlikely to transmit disease. The neurotoxins responsible for tick paralysis also are found in tick saliva.

The local physiologic changes associated with tick feeding produce the characteristic 1- to 4-mm erythematous mark typically seen on the skin after a tick bite. This is a common finding from most blood-sucking arthropods. The mark should not be confused with certain rashes associated with disease progression—for example, erythema migrans. Informing patients of this difference may be reassuring.

### Lyme Disease

**Perspective**

Lyme disease, the most common vector-borne disease in the United States, is a tick-borne illness caused by the spirochete *Borrelia burgdorferi*. The story of Lyme disease begins in 1975, when health officials at Connecticut’s State Department of Health and physicians at Yale University were alerted by two skeptical mothers to an unusually large number of cases of apparent juvenile rheumatoid arthritis (JRA) occurring in their small coastal community of Old Lyme, Connecticut. Investigation led to the description of a “new” entity called *Lyme arthritis.*

Lyme disease occurs worldwide and has been reported on every continent except Antarctica. It now accounts for more than 95% of all reported cases of vector-borne illness in the United States. The actual overall incidence of Lyme disease is unknown, because many cases go unreported. Lyme disease occurs in people of all ages but is more common in children younger than 15 years and in adults 30 to 60 years of age.

Persons at greatest risk live or vacation in endemic areas. In the United States, three distinct endemic foci are recognized: the northeastern coastal, mid-Atlantic, and north central states. During 2000, a total of 17,730 cases of Lyme disease were reported from 44 states and the District of Columbia. Twelve states—Connecticut, Rhode Island, New Jersey, New York, Delaware, Pennsylvania, Massachusetts, Maryland, Wisconsin, Minnesota, New Hampshire, and Vermont—accounted for 95% of cases reported in the nation (Fig. 132-3).

The principal tick vectors are *I. scapularis* in the Northeast and Midwest and *Ixodes pacificus* in the West. Nymphal *Ixodes* ticks satisfy all known epidemiologic requirements for the zoonosis as it exists in nature. There is no compelling evidence for alternate arthropod vectors of infection.

The *I. scapularis* population density depends on that of its preferred hosts: the white-footed field mouse, *Peromyscus leucopus*, for the larval and nymphal forms and the white-tailed deer, *Odocoileus virginianus*, for the adult form. The white-footed mouse readily becomes infected after being bitten by infected ticks and remains highly infectious for periods of time that approach its life span in nature, thereby providing an important reservoir for *B. burgdorferi*. Adult *I. scapularis* ticks feed primarily on deer, which are key hosts in the tick life cycle and in whose fur the adult tick may survive the winter. The relatively recent repopulation of several areas in the

Figure 132-2. Identification scheme for genera within Ixodidae and Argasidae, the two primary disease-transmitting families of ticks.

United States by white-tailed deer preceded the recent emergence of Lyme disease in those regions. Although all stages of the tick may feed on humans, the nymph is primarily responsible for the transmission of Lyme disease. It is not surprising that more than two thirds of patients with Lyme disease do not recall a tick bite, in view of the small size (1 to 2 mm) of nymphs (Fig. 132-4). The nymph feeds in the spring and summer, which correlates with a peak incidence of early Lyme disease occurring between May and August. In addition, recreational and occupational exposure is greatest during this time. Later manifestations of Lyme disease may appear throughout the year.

**Principles of Disease**

The spirochete *B. burgdorferi* persists and multiplies in the midgut of its tick vector, *I. scapularis*. Transmission of the spirochete to humans occurs during feeding, generally 2 days after attachment. The mechanism of transmission probably is inoculation with infectious saliva or, alternatively, with tick gut fluids periodically regurgitated during the feeding process.

After an incubation period that lasts several days to several weeks, spirochetemia develops, and *Borrelia* organisms may
migrate outward in blood or lymph to virtually any site in the body. The spirochete appears to be tropic for synovial tissue, skin, and cells of the nervous system, but the mechanism of this tropism is not yet understood. Infection by the spirochete itself accounts for early clinical manifestations. It remains unclear whether late disease manifestations require the continued presence of viable spirochetes or whether an ongoing host immune response to initial infection is sufficient to cause some late disease manifestations. Although the exact roles of infecting spirochetes, spirochetal antigens, and host immune responses are unknown, it is likely that persistent live spirochetes are responsible for most later manifestations of the disease. The variable severity of Lyme disease may in part result from genetic variations in the human immune system. Patients with chronic Lyme arthritis have an increased frequency of human leukocyte antigen (HLA) specificity—in particular, for HLA-DR4 and, less often, HLA-DR2.

Clinical Features

Lyme disease, a multisystem disorder, can be classified into three stages: early localized, early disseminated, and late disease. Virtually any clinical feature may occur alone or recur at intervals, and some patients who had no early symptoms may have late symptoms. The disorder usually begins with a rash and associated constitutional signs and symptoms, suggesting a “viral syndrome” (early Lyme disease). Neurologic, joint, or cardiac manifestations may emerge weeks to months later (early disseminated Lyme disease), and chronic arthritic and neurologic abnormalities may appear weeks to years later (late Lyme disease). The time course for the clinical features of untreated Lyme disease is illustrated in Figure 132-5.

Early Lyme Disease

Ticks may attach to human hosts at the initial point of contact (generally around ankle level) or may move about until they encounter an obstruction. The groin, popliteal fossae, gluteal folds, axillary folds, and ear lobes are common sites of attachment. After transmission of *B. burgdorferi* through a tick bite, the initial site of infection is the skin at the site of the bite. After an incubation period of approximately 1 week (range, 1 to 36 days), the spirochetes cause a gradually spreading localized infection in skin and a resultant skin lesion, erythema migrans. Erythema migrans is the most characteristic clinical manifestation of Lyme disease and is recognized in 90% or more of patients. Erythema migrans may go unnoticed if the entire skin surface is not examined. The characteristic rash begins at the site of the tick bite with an erythematous papule or macule. The lesion expands gradually (1 to 2 cm/day, a rate of expansion slower than that of cellulitis). The patch of erythema may be confluent or may have bands of normal-appearing skin. Central clearing may occur but is not an invariable feature. The lesion borders usually are flat but may be raised. The lesions generally are sharply demarcated and blanch with
pressure. Most lesions are oval or round, but triangular and elongated patches may occur. In patients presenting 1 to 7 days after the appearance of lesions, the average lesion size is approximately 8 by 10 cm (range, 2 by 3 cm to 25 by 25 cm). In some cases, the center of some early lesions becomes red and indurated or vesicular and necrotic. The lesion is warm to the touch and may be described by the patient as nontender to minimally tender (Fig. 132-6).

Hematogenous spread of viable spirochetes (not additional tick bites) may result in one or more secondary lesions. These secondary lesions are smaller, migrate less, and typically spare the palms and soles. In all, 10 to 15% of patients have more than 20 such lesions; on rare occasions they may number more than 100. Blistering and mucosal involvement do not occur. The primary and secondary skin lesions generally fade after approximately 28 days (range, 1 week to 14 months) without treatment and within several days of antibiotic therapy. Recurrent lesions may develop in patients who do not receive antibiotic therapy, but apparently not in those who receive appropriate antibiotics.

Constitutional signs and symptoms commonly appear in early Lyme disease. Malaise, fatigue, and lethargy are most common (seen in approximately 80% of patients) (Table 132-2) and may be severe. Fever typically is low grade and intermittent. Lymphadenopathy usually is regional in the distribution of erythema migrans or may be generalized; splenomegaly may occur. Musculoskeletal complaints, such as arthralgias and myalgias, are common, and the discomfort typically is short-lived and migratory, sometimes lasting only hours in one location. Frank arthritis may occur at this stage but is rare.

Clinical manifestations of meningeal irritation are frequently seen. Headache, the most common symptom, usually is intermittent and localized. Nausea, vomiting, and photophobia occasionally accompany the headache. Kernig’s and Brudzinski’s signs typically are absent, and neck stiffness usually is noted only on extreme forward flexion. At this stage, the neurologic examination and cerebrospinal fluid (CSF) assessment (usually) both yield normal findings.

Signs and symptoms of hepatitis, including anorexia, abdominal pain, right upper quadrant tenderness, nausea, and vomiting, may be present. Mild pharyngitis also may be present, but other upper respiratory symptoms such as rhinorrhea do not occur. Although the systemic symptoms of early Lyme disease often are described as “flulike,” this term can be misleading because clinically significant cough usually does not occur. Conjunctivitis develops in approximately 10% of patients.

The incidence of Lyme disease without erythema migrans appears to be approximately 10%. Because of the variety of nonspecific signs and symptoms at this stage, in the absence of the characteristic rash or history of tick bite, early Lyme disease may be easily confused with a viral or collagen-vascular disease. The intermittent and rapidly changing nature of the early signs and symptoms of Lyme disease may be a helpful distinguishing feature, especially in a patient from an endemic area. In untreated disease, early symptoms usually last for several weeks but may persist for months.

*Required for inclusion in this study.

Acute Disseminated Infection

Shortly after disease onset, hematogenous spread can cause a variety of systemic signs and symptoms and result in secondary sites of infection. Organ systems commonly affected are the nervous system, heart, and joints. Less commonly, the eyes, liver, skeletal muscle, subcutaneous tissue, and spleen are infected.

Neurologic Manifestations

A relatively symptom-free interval usually occurs between early and disseminated infection; however, neurologic signs and symptoms may be the presenting manifestations of Lyme disease or may overlap with early or late manifestations. Beginning at an average of 4 weeks (range, 0 to 10 weeks) after the onset of erythema migrans, neurologic involvement occurs in approximately 15% of untreated patients.

The most common neurologic manifestation of Lyme disease is a fluctuating meningoencephalitis with superimposed symptoms of cranial neuropathy, peripheral neuropathy, or radiculopathy. A triad of meningitis, cranial neuropathies (usually Bell’s palsy), and radiculopathy has been described, but each entity may occur alone. Headache of variable intensity usually is present; other signs and symptoms of a mild meningoencephalitis may be noted, including lethargy or irritability, sleep disturbances, poor concentration, and memory loss. At this point, the disease often is misdiagnosed as viral meningitis. As in early disease, Kernig’s and Brudzinski’s signs are absent and computed tomography (CT) findings are normal. Unlike in early disease, however, findings on CSF examination often are abnormal, with a lymphocytic pleocytosis and elevated protein level. CSF glucose concentration usually is normal. Intrathecal B. burgdorferi antibody (usually immunoglobulin G [IgG] or IgA) is present in 80 to 90% of patients. CSF polymerase chain reaction (PCR) assay results are positive in less than one half of patients.13 Cranial neuropathies are common, occurring in approximately 50% of patients with Lyme meningitis; usually the seventh nerve is involved. Other cranial nerves are affected less often. Bell’s palsy is bilateral in approximately one third of patients. Its duration usually is from weeks to months, and the condition generally resolves spontaneously without treatment.

Peripheral nervous system manifestations also may occur in early disseminated Lyme disease. The spinal root and plexus and the peripheral nerves may be involved in the form of thoracic sensory radiculitis, brachial plexitis, mononeuritis, and motor radiculoneuritis in the extremities. Patients may complain of weakness, pain, or dysesthesia. Examination may reveal loss of reflexes. Involvement of the extremities usually is asymmetrical, but cervical and thoracic dermatomes may be affected. Other rare neurologic abnormalities described in association with Lyme disease include chorea, transverse myelitis, ataxia, and pseudotumor cerebri.
Cerebral vasculitis associated with Lyme disease also has been reported.

Cardiac Manifestations

Cardiac involvement in Lyme disease is uncommon. Estimates of the incidence of carditis in untreated patients who have Lyme disease range from 4 to 10%. The average time from initial illness to the development of carditis typically is 3 to 5 weeks (range, 4 days to 7 months). Direct myocardial invasion has been demonstrated with endomyocardial biopsy. Electrophysiologic testing has demonstrated widespread involvement of the conduction system.

The most common cardiac manifestation of Lyme disease is atrioventricular (AV) block, although conduction defects may involve any level of the conducting system. Myopericarditis, tachydysrhythmias, and ventricular impairment occur less often. In a review of 105 reported cases of Lyme carditis, 49% of cases were third-degree AV block, 16% were second-degree, and 12% were first-degree. The degree of AV block seen in a specific patient may fluctuate rapidly.

A commonly observed feature of AV block in patients with Lyme carditis is its gradual resolution, resembling that occurring after an acute inferior wall myocardial infarction and presumably related to the resolution of inflammation. Assessment of the level of the AV block is important to determine the prognosis of a patient with Lyme carditis. In most cases, block appears to be at or above the level of the AV node; therefore, the prognosis is favorable. However, infranodal AV block does occur and may be characterized by slow escape rhythms of wide QRS pattern, asystole, or fluctuating left and right bundle branch block. Other electrocardiographic findings include nonspecific ST- and T-wave abnormalities and intraventricular conduction delay.

Patients with high-degree AV block usually are asymptomatic. Symptoms include light-headedness, palpitations, syncope, chest pain, and dyspnea on exertion. Physical examination may reveal flow murmurs and murmurs of mild mitral regurgitation, pericardial friction rub, or evidence of congestive heart failure. Associated left ventricular dysfunction may be present and has been documented by two-dimensional echocardiography and radionuclide studies; in most reported cases, it has been mild and transient.

Arthritis

Although classically considered a sign of late Lyme disease, acute arthritis may begin during the acute disseminated stage. Monarticular or oligoarticular arthritis, primarily affecting large joints, especially the knee, may develop weeks to months after the onset of initial illness. In an early study of the natural history of Lyme arthritis, approximately 50% of untreated patients experienced one episode or multiple intermittent attacks of arthritis. Acute arthritis typically is monoarticular, with involvement of only one knee. The shoulder, elbow, temporomandibular joint, ankle, wrist, hip, and small joints of the hands and feet are involved less commonly. Episodes of arthritis typically are brief (lasting weeks to months) and separated by variable periods of remission.

Arthrocentesis generally is nondiagnostic, yielding an inflammatory synovial fluid with a mean white blood cell count of approximately 25,000 cells/μL (75% polymorphonuclear leukocytes). Higher WBC counts have been reported, simulating septic arthritis. The synovial glucose concentration usually is normal, and protein levels are variable, ranging from 3 to 8 g/dL. Cultures of the fluid rarely identify the causative spirochete. Complement level generally is greater than one third that of serum. Synovial biopsy reveals hypertrophy, vascular proliferation, and a mononuclear cell infiltrate. Findings therefore are similar to those in rheumatoid arthritis, except that rheumatoid factor and antinuclear antibody assays yield a negative result in Lyme arthritis. Radiography may reveal nonspecific abnormalities such as juxta-articular osteoporosis, cartilage loss, cortical or marginal bone erosions, and joint effusions.

Ophthalmic Manifestations

Ocular involvement also may be seen in early disseminated disease, with manifestations including conjunctivitis, keratitis, choroiditis, retinal detachment, optic neuritis, and blindness. These findings also may be seen in late disease.

Late Lyme Disease

The chronic phase of Lyme disease is characterized by arthritic and, less commonly, neurologic symptoms. Transition from a pattern of episodic inflammation in early disease to a more indolent persistent inflammation is observed over time. The term chronic (or late) Lyme disease is used to describe continuous inflammation in an organ system for more than 1 year.

A pattern of exacerbation and remission of arthritis may extend over several years, with a gradual tendency toward less frequent and less severe occurrences. The spontaneous long-term remission rate approximates 10 to 20% annually in untreated patients. However, patients commonly have episodes of periartricular involvement, arthralgias, or fatigue interspersed between attacks of frank arthritis. During the second or third year of illness, attacks of joint swelling sometimes become longer in duration, lasting months rather than weeks. Chronic arthritis eventually develops in approximately 10% of patients.

Late neurologic complications include a wide variety of abnormalities of the central and peripheral nervous systems, as well as fatigue syndromes. Diagnosis may be difficult because of the large number of other neurologic conditions that Lyme disease may imitate and because late neurologic symptoms may be the first symptoms of the disease. The manifestations of chronic neuroborreliosis usually appear months to years after the onset of infection.

The most common late neurologic manifestation of Lyme disease is a chronic encephalopathy that manifests as a mild to moderately severe impairment of memory and learning, Hypersomnolence and mild psychiatric disturbances (depression, irritability, or paranoia) also may develop.

Peripheral nervous system manifestations often are seen in late disease, with involvement of cranial nerves, spinal roots, spinal plexuses, and peripheral nerves. A predominantly sensory polyradiculoneuropathy that manifests as either radicular pain or distal paresthesias is common. Significant overlap occurs with early symptoms. Less commonly, a demyelinating condition resembling multiple sclerosis may appear in late disease. Symptoms are variable and, as in multiple sclerosis, may undergo exacerbations and remissions. CT and magnetic resonance imaging (MRI) may reveal multiple white matter lesions.

Chronic inflammation also may occur in the skin, causing a seldom-recognized late cutaneous manifestation of Lyme disease, acrodermatitis chronica atrophicans. This condition usually involves the skin of distal extremities at the site of a tick bite. It is characterized in its initial stages by an edematous infiltration, which progresses to an atrophic lesion resembling localized scleroderma in its more established form. B. burgdorferi has been demonstrated in the skin of patients with acrodermatitis chronica atrophicans as well as positive findings on serologic studies.
Diagnostic Strategies

The diagnosis of Lyme disease is based primarily on clinical and epidemiologic features, and identification of the disorder often is difficult, especially in the early stage. A history of tick bite is elicited in only approximately one third of cases. Erythema migrans is present in most patients and, in endemic areas, is considered diagnostic. Isolated late symptoms may emerge months after the initial infection, however, and the patient may not recall the rash. The disease should be considered in patients who live in or have visited an endemic area and who present during the summer months with nonspecific symptoms suggesting a viral illness or meningitis. In addition, the development of monarticular arthritis, multiple neurologic abnormalities, or heart block in previously healthy patients should raise the suspicion of Lyme disease.

Results of routine laboratory studies are nonspecific and such studies generally are not helpful in diagnosing Lyme disease. Abnormalities may include an elevated erythrocyte sedimentation rate, mild anemia, total WBC count in the normal range with a decreased absolute lymphocyte count, microhematuria, proteinuria, and increased alanine transferase level. Cultures of blood, tissue, and body fluids (including CSF and synovial fluid) for B. burgdorferi and direct visualization techniques are difficult to perform properly and have such a low yield that they are not clinically useful. Serologic testing is the most practical and useful means of confirming a clinical diagnosis of Lyme disease, but it is not without limitations. Results of serologic tests must be interpreted cautiously within the clinical context, and such tests should be regarded as only adjuncts in the diagnostic process. Current serologic tests measure host antibody response (for both IgG and IgM) to B. burgdorferi. Problems with the performance of these tests and interpretation of findings often result in diagnostic confusion. False-negative and especially false-positive results are common. The antibody response to B. burgdorferi develops slowly. The peak of IgM titers appears between 3 and 6 weeks after the onset of illness. Earlier in the course of the illness, IgM titers may be negative. IgM usually returns to nondiagnostic levels 4 to 6 weeks after their peak, but elevations may persist. IgG antibody may be detectable 2 months after exposure and peaks at approximately 12 months. Early antibiotic therapy may blunt or even abolish the antibody response. During the first month of illness, both IgM and IgG titers should be determined, preferably in acute and convalescent serum samples. In approximately 20 to 30% of patients, a positive response occurs with acute samples, whereas even after antibiotic treatment, a positive response occurs with convalescent samples obtained 2 to 4 weeks later in approximately 70 to 80% of patients. After that time, most patients demonstrate a positive IgG antibody response, and a single test usually is sufficient.

In patients with illness lasting longer than 1 month, a positive IgM test result alone is likely to be false positive. Therefore, a positive IgM response should not be used to support the diagnosis after the first month of infection. Testing with the enzyme-linked immunosorbent assay (ELISA) is the cornerstone of laboratory diagnosis of Lyme disease. Although ELISA alone has a sensitivity of 89% and a specificity of 72%, a positive test result in patients with a low pretest probability (i.e., less than 0.20) of Lyme disease is more likely to be a false positive than a true positive. In patients with a positive or equivocal ELISA result, a confirmatory Western blot assay should be ordered. Specimens that yield a negative result on ELISA are not tested further. Criteria for positive Western immunoblotting (requiring the presence of bands at particular locations) have been adopted by the CDC.

IgG (and occasionally IgM) antibody may persist for several years after adequate treatment and symptom resolution. Persistent seropositivity is not diagnostic of ongoing infection. Even an IgM response cannot be interpreted as a demonstration of recent infection or reinfection unless the appropriate clinical characteristics are present. IgG antibody developed after natural infection does not always confer immunity against future infection by B. burgdorferi. Patients who are treated for erythema migrans may become reinfected; patients with Lyme arthritis, however, usually have high antibody titers to many spirochetal proteins and seem not to become reinfected.

False-positive ELISA results are common. Serologic cross-reactivity can occur between B. burgdorferi and other spirochetes, most notably Treponema pallidum. False-positive results for Lyme disease also can occur with relapsing fever, gingivitis, leptospirosis, enteroviral and other viral illnesses, rickettsial diseases, autoimmune diseases, malaria, and subacute bacterial endocarditis. In addition, it is estimated that up to 5% of the normal population will “test positive” for Lyme disease by ELISA. Bayes’ theorem states that if the pretest likelihood of the disease is low, then the positive predictive value is low. A positive test result is more likely to be a false-positive result. For this reason, screening serologic tests are not indicated in the absence of objective clinical evidence of Lyme disease.

Patients suspected of having acute Lyme neuroborreliosis should be evaluated with serologic tests and routine CSF examination. Paired serum and CSF samples should be obtained to evaluate for intrathecal production of antibody, although most patients with neuroborreliosis have positive results on serum serologic testing, thereby making additional laboratory confirmation with CSF serology unnecessary. Polymerase chain reaction (PCR) assay is superior to culture for the detection of B. burgdorferi in synovial fluid and has a sensitivity of 73% and specificity of 99% in untreated Lyme arthritis.

Differential Considerations

Although Lyme disease manifests in many ways, each stage has characteristic clinical findings that are helpful in narrowing the scope of a differential diagnosis that at first may seem overwhelmingly broad. Early Lyme disease (erythema migrans and associated constitutional symptoms) may be easily confused with a variety of other diseases, especially if the characteristic rash of erythema migrans is absent. A common clinical presentation is a flu-like illness with headache, nausea, fever, chills, myalgias, arthralgias, stiff neck, and anorexia, occurring during the summer months. Even in endemic areas during the summer months, most patients with such symptoms do not have Lyme disease. When headache and stiff neck are the predominant symptoms, the principal diagnostic distinction to be made is between Lyme disease and the enteroviral diseases (and other causes of aseptic meningitis). The enteroviral diseases also have their peak incidence during the summer months; however, diarrhea, commonly associated with enteroviral infection, is not a feature of Lyme disease. Abdominal pain, anorexia, and nausea suggest hepatitis; sore throat, adenopathy, and fatigue suggest mononucleosis; and myalgias and arthralgias suggest connective tissue diseases.

The rash of erythema migrans is characteristic of but not pathognomonic for Lyme disease. Some patients are not aware of having had such a rash, and in others, its appearance is atypical. Secondary lesions may be confused with the target lesions of erythema multiforme, which generally are smaller and nonexpanding. Erythema multiforme also may involve the mucous membranes, palms, and soles; erythema migrans does not. The presence of a malar rash in association with Lyme
disease suggests systemic lupus erythematosus. Erythema nodosum generally causes more painful induration than erythema migrans and has a predilection for the extensor surfaces of the legs. Erythema marginatum of acute rheumatic fever also is in the differential diagnosis for erythema migrans; the Lyme disease rash differs in comprising generally fewer, larger, less evanescent lesions that migrate more slowly.\textsuperscript{35} Atypical erythema migrans manifesting as an urticarial rash may suggest hepatitis B infection or serum sickness. Other cutaneous entities in the differential diagnosis for erythema migrans include cellulitis, fungal infection, fixed drug-related eruptions, plant dermatitis, and insect or spider bites. Lyme disease must be considered in a patient with any atypical rash accompanied by a “viral syndrome” or meningitis-like illness, especially during the months of peak incidence.

Acute rheumatic fever, coronary artery disease, or viral myocarditis may be suggested by the cardiac manifestations of Lyme disease. The carditis of Lyme disease, like the carditis of rheumatic fever, may follow pharyngitis and migratory polyarthritis. Erythema marginatum usually occurs with the onset of arthritis, in contrast with erythema migrans, which usually precedes the carditis. Although some patients with Lyme disease may satisfy the clinical aspects of the Jones criteria for acute rheumatic fever, they lack evidence of a preceding streptococcal infection; in addition, valvular involvement is not a prominent feature of Lyme carditis.

The differential diagnosis of the neurologic manifestations caused by Lyme disease is extensive. Considerations include aseptic meningitis, herpes simplex encephalitis, Bell’s palsy of other causes, multiple sclerosis, Guillain-Barré syndrome, dementia, primary psychosis, cerebral vasculitis, and brain tumor. Neurologic symptoms often occur in the absence of any epidemiologic clues or preceding clinical symptoms suggestive of Lyme disease, making the diagnosis particularly challenging.

Lyme arthritis may mimic other immune-mediated disorders. The arthritis of Lyme disease generally is asymmetric, oligoarticular, and episodic. In contrast to patients with rheumatoid arthritis, those with Lyme arthritis rarely have symmetric polyarthritis, morning stiffness, a positive result on rheumatoid factor assay, or subcutaneous nodules. Lyme arthritis commonly is mistaken for seronegative rheumatoid arthritis; however, Lyme arthritis is most similar to the spondyloarthropathies, particularly reactive arthritis.\textsuperscript{36} Lyme disease and Reiter’s syndrome both commonly cause huge knee effusions, but in Lyme disease, absence of the extraarticular features of Reiter’s syndrome (conjunctivitis, urethritis or cervicitis, balanitis, keratosis blennorrhagica) at the time of the arthritis helps distinguish it from Reiter’s syndrome. In children, Lyme arthritis may mimic juvenile rheumatoid arthritis, but joint involvement in Lyme disease usually occurs in short, intermittent attacks, and iridocyclitis typically is absent. Rheumatoid factor titers will be negative in both juvenile rheumatoid arthritis and Lyme disease. The diseases resemble one another closely enough to have been confused at the time of the initial description of Lyme disease. Other diseases in the differential diagnosis for Lyme arthritis include acute gouty arthritis, septic arthritis, gonococcal arthritis, rheumatic fever, polymyalgia rheumatica, and the temporomandibular joint syndrome.

**Management**

Prompt treatment of early disease can shorten the duration of symptoms and prevent progression to later stages of disease. Most of the various manifestations of Lyme disease can be treated successfully with oral antibiotic therapy, with the exception of neurologic abnormalities, which usually require intravenous therapy. Treatment of Lyme disease is summarized in Table 132-3.

**Vaccination**

No vaccine against Lyme disease is currently available in the United States. The LYMErix vaccine (SmithKline Pharmaceuticals, Philadelphia), initially licensed in 1999, was withdrawn from the market in 2002. The vaccine, directed against the outer surface protein A of *B. burgdorferi* (OspA), was apparently safe and efficacious but required multiple and repeated doses for optimal protection. Ongoing questions about its safety and cost-effectiveness dampened demand for the vaccine.\textsuperscript{37}

A history of vaccination with the previously licensed vaccine should not change the approach to ED management. Because protective immunity produced by the vaccine is short-lived, it is unlikely that previous vaccination will provide any residual protective effect. Vaccination may cause a persistently positive ELISA result but a negative Western blot result.

**Prophylaxis and Asymptomatic Tick Bites**

Although previous expert consensus has recommended that persons bitten by deer ticks (I. *scapularis*) should not routinely receive antimicrobial chemoprophylaxis,\textsuperscript{5} this recommendation should be modified in accordance with the findings of a well-designed trial in which a single 200-mg dose of doxycycline effectively prevented Lyme disease when given within 72 hours after tick bite.\textsuperscript{37} A single 200-mg dose of doxycycline should be considered for adult patients and children 8 years of age and older (4 mg/kg, up to a maximum dose of 200 mg) when all of the following criteria are met: (1) the tick is an adult or nymphal *I. scapularis*, (2) the tick has been attached for 36 hours or more as indicated by certainty of the time of exposure or the degree of engorgement, (3) prophylaxis can be started within 72 hours after tick removal, (4) the local rate of infection of these ticks with *B. burgdorferi* is 20% or greater, and (5) doxycycline is not contraindicated. Infection rates of 20% or greater of ticks with *B. burgdorferi* generally are reported from highly endemic areas such as New England, parts of the mid-Atlantic region, and parts of Minnesota and Wisconsin. Most other areas of the United States do not have infection rates high enough to warrant prophylaxis.\textsuperscript{3}

The efficacy of single-dose doxycycline in patients who present more than 72 hours after removing a tick is unknown. In children, dosing and efficacy of prophylactic treatment have not been evaluated. The effectiveness of doxycycline for the prevention of other infections transmitted by *I. scapularis* ticks (e.g., babesiosis, human granulocytic ehrlichiosis) is unknown and should not be assumed.\textsuperscript{37} Other antimicrobial agents that are effective for the treatment of Lyme disease (e.g., amoxicillin) and even other regimens of doxycycline (e.g., 100 mg twice daily) have unknown efficacy for Lyme disease prophylaxis.

Bites from *Dermacentor variabilis* and *Amblyomma americanum* do not require prophylactic treatment. Any patient who has been bitten by a tick should be instructed to seek medical evaluation if symptoms of tick-borne illness develop.

**Early Disease**

Prompt antibiotic therapy is essential in early Lyme disease because it generally shortens the duration of the rash and associated symptoms and, more important, prevents later illness in most patients. Some patients with severe early

*Pediatric dosage should not exceed adult dosage.
†Tetracycline, 250 to 500 mg PO qid, may be substituted for doxycycline. Neither doxycycline nor any other tetracycline should be used for children younger than 8 years of age or for pregnant or lactating women.
‡Regimens for radiculoneuropathy, peripheral neuropathy, and encephalitis are the same as those for meningitis.
§Oral regimens are reserved for mild cardiac involvement (see text).

disease, however, progress to later stages despite appropriate antibiotic regimens.

The drug of choice for men, nonpregnant and nonlactating women, and children older than 8 years of age is doxycycline, 100 mg twice daily for 3 weeks. An advantage of doxycycline is that it also is effective for treatment of human granulocytic ehrlichiosis, which is transmitted by the same tick that transmits Lyme disease. Pregnant or lactating women and children younger than 8 years of age should receive amoxicillin, 500 mg PO (20 to 40 mg/kg per day in three doses for children). Cefuroxime axetil has been shown to be as effective as doxycycline or amoxicillin and may be used in children of any age, but cephalexin is ineffective in Lyme disease.

Macrolide antibiotics are not recommended as first-line agents for therapy for early Lyme disease. They should be reserved for patients who cannot tolerate doxycycline, amoxicillin, and cefuroxime axetil. Macrolide regimens for adults include azithromycin, 500 mg PO daily for 7 to 10 days; erythromycin, 500 mg PO four times daily for 14 to 21 days; and clarithromycin, 500 mg PO twice daily for 14 to 21 days.

A Jarisch-Herxheimer–type reaction may occur in the first 24 hours of antibiotic treatment, consisting of fever, chills, myalgias, headache, tachycardia, increased respiratory rate, and mild leukocytosis. Defervescence usually takes place within 12 to 24 hours, and the patient’s symptoms can be managed with bedrest and aspirin. The pathogenesis of this reaction is controversial, but it probably is caused by the killing of spirochetes with release of pyrogens. The Jarisch-Herxheimer reaction occurs more commonly with penicillin and doxycycline than with erythromycin, probably because of their superior spirochetalic activity.

### Early Disseminated Infection

#### Neurologic Disease

For patients with relatively mild symptoms (e.g., solitary facial nerve palsy with normal findings on CSF examination), doxycycline or amoxicillin can be used in the same dosage as for early disease, but the duration of therapy should be extended to 30 days. The use of prednisone for facial nerve palsy from Lyme disease has been suggested but is not currently recommended.

For patients with other objective neurologic abnormalities (e.g., meningitis or encephalitis, peripheral neuropathies, cranial neuritis other than facial nerve palsy) or evidence of the spirochete in the CSF, parenteral antibiotic therapy is required. Ceftriaxone, 2 g/day IV for 14 days (75 to 100 mg/kg/day for pediatric patients), or penicillin G, 18 to 24 million
units daily IV for 10 to 14 days, may be used. Ceftriaxone may be more effective than penicillin, and many experts recommend longer courses (e.g., up to 4 weeks). In cases of penicillin or cephalosporin allergy, oral doxycycline for 30 days may be used.

**Cardiac Disease**

Patients with mild cardiac conduction system involvement (first-degree AV block with a PR interval less than 0.30 second) and no other significant symptoms usually can be treated safely on an outpatient basis with oral doxycycline or amoxicillin for 21 to 30 days. Patients with higher degrees of AV block, including first-degree block with a PR interval greater than 0.30 second or evidence of global ventricular impairment, should be hospitalized for cardiac monitoring and treatment with parenteral antibiotics. Either penicillin G, 18 to 24 million units IV, or ceftriaxone, 2 g daily for 21 days (50 to 80 mg/kg/day for children), may be used.

The benefit of adjunct use of aspirin or prednisone in treating Lyme carditis is uncertain. Temporary cardiac pacing may be necessary in patients who have severe heart block with hemodynamic instability. The block generally resolves completely with antibiotic treatment, so the recognition of Lyme carditis in young patients with unexplained heart block is critical to avoid unnecessary permanent pacemaker implantation.

**Late Infection**

**Arthritis**

In established Lyme arthritis, the response to antibiotic therapy may be delayed for several weeks or months. Thirty-day oral regimens such as doxycycline, 100 mg PO twice daily, or amoxicillin, 500 mg three times daily, usually are effective and, for reasons of cost and convenience, may be selected as first-line therapy given on an outpatient basis before use of parenteral antibiotic therapy is considered. Persistent or recurrent joint swelling after recommended courses of antibiotic therapy can be treated with another 4-week course of oral antibiotics or with a 2- to 4-week course of intravenous ceftriaxone. A small percentage of patients with Lyme arthritis, particularly those with HLA-DR4 specificity or antibody reactivity with OspA, may have persistent joint inflammation despite treatment with either oral or intravenous antibiotics. Such patients often do not respond to any antibiotic therapy and may require arthroscopic synovectomy.

**Neurologic Disease**

Patients with late neurologic disease affecting the central or peripheral nervous system should be treated with ceftriaxone (2 g once a day intravenously for 2 to 4 weeks). Alternative parenteral therapy may include cefotaxime (2 g IV every 8 hours) or penicillin G (18 million to 24 million units daily, given in divided doses every 4 hours). Response to treatment is usually slow and may be incomplete.

**Lyme Disease and Pregnancy**

Similar to the spirochetal agents of syphilis and relapsing fever, *B. burgdorferi* can be passed transplacentally. In rare cases, Lyme disease acquired during pregnancy may lead to infection of the fetus and possibly to stillbirth, but adverse effects on the fetus have not been documented conclusively. Counseling the termination of a pregnancy because of maternal Lyme disease is unwarranted.

Lyme disease contracted during pregnancy can be treated and cured. Treatment for pregnant patients can be identical to that for nonpregnant patients with the same disease manifestations, except that doxycycline should be avoided. Most women give birth to normal infants despite documented Lyme borreliosis during their pregnancies.

**RELAPSING FEVER**

**Perspective**

Relapsing fever is caused by bacteria of the *Borrelia* species, order Spirochaetales. Human *Borrelia* infections occur worldwide and all are associated with arthropod vectors. The epidemic (louse-borne) form of relapsing fever is caused solely by *Borrelia recurrentis* and is found mostly in Africa, where mortality rates can reach 70% with outbreaks. The endemic form, tick-borne relapsing fever, is caused by a group of closely related *Borrelia* species, their names derived from the species names of *Ornithodoros* tick vectors that carry them. The more common ones in North America are *Borrelia hermsii*, *Borrelia turicatae*, and *Borrelia parkeri*. *B. burgdorferi* has been recognized as the etiologic agent of the third and most recently described borrelial disease, Lyme disease.

**Principles of Disease**

Tick-borne relapsing fever is maintained in an animal reservoir consisting primarily of wild rodents, including squirrels, mice, rats, chipmunks, and rabbits. It is found predominantly at altitudes of 2000 to 7000 feet in coniferous forest habitats. The tick vectors are argasids belonging to several species of the genus *Ornithodoros*, which routinely reside in the nests and burrows of their mammalian hosts. Ticks acquire the infection by feeding on a spirochetemic rodent. The borreliae remain viable in the ticks for several years and can be passed transovarially to the next generation; thus, the tick is a major reservoir and vector. These soft ticks feed for brief periods (15 to 30 minutes), usually at night, and their painless bite generally is unnoticed by the sleeping victim. Transmission occurs by injection of infected saliva through the bite site or intact skin. Less common modes of transmission (e.g., by way of venipuncture equipment in intravenous drug users) have been reported.

In the United States, relapsing fever occurs primarily in the western Mountain and Pacific states, including Montana, Wyoming, Nevada, Colorado, California, and Washington. Persons who come in contact with infected ticks from wild rodents are at greatest risk. Outbreaks have been reported among groups of persons sleeping overnight in hunting cabins inhabited by wild rodents.

In tick-borne relapsing fever, the initial febrile episode lasts 3 days. This is followed by an asymptomatic period of variable duration but usually approximately 7 days, during which patients generally feel better and may return to their usual daily activity levels under the assumption that they have recovered from another viral illness. Relapse then occurs, with symptoms that mimic those of the original illness. With tick-borne relapsing fever, this cycle repeats itself three to five times. Each successive relapse usually is less severe. Relapse is caused by the spirochete’s unique ability to undergo antigenic variation within the body of the infected host. Each successive antigenic variation is cleared from the bloodstream by specific host antibodies, and a characteristic relapsing febrile course results.

Clinical illness manifests in two classic stages as each fever episode resolves. The first stage is called the “chill” phase (high fevers with reported temperatures of to 106.7°F, mental status changes, tachycardia, and tachypnea) lasting approximately 30 minutes, followed by a “flush” phase (rapid tem-
**Clinical Features**

After a postbite incubation period of 4 to 18 days, during which time the host concentration of spirochetes increases, fever of abrupt onset occurs, often accompanied by shaking chills, headache, arthralgias, myalgias, nausea, and vomiting. Occasionally a pruritic eschar may be noted at the site of the tick bite, but this usually is absent by the onset of clinical symptoms. Consequently, the nonspecific nature of the clinical presentation often leads to misdiagnosis of the disease as a viral illness. The patient's temperature is high, and generalized muscle weakness and lethargy are common. Hepatomegaly, splenomegaly, and jaundice are sometimes seen. Neurologic involvement is less common but can manifest as delirium, nuchal rigidity, peripheral neuropathy, or pupillary abnormalities. Uveitis has been described. A macular or petechial skin rash, more apparent on the trunk than on the extremities, may be present.

Recent severe cases of tick-borne relapsing fever resulting in ARDS in California and Nevada near the Lake Tahoe area and in the state of Washington prompted a comprehensive epidemiologic investigation of cases in those areas over a 10-year period. This study showed that ARDS may be more common than was previously suspected. Reported occurrence rates for Jarisch-Herxheimer reaction were between 6% and 21%; for hypoxia, 16%; for elevated liver function test values, 8%; and for ARDS, 6%. Forty-six percent of the patients required hospitalization.

**Diagnostic Strategies**

The definitive diagnosis of relapsing fever depends on the demonstration of spirochetes in the peripheral blood during a febrile episode. This is not a typical finding with other spirochetal diseases. In most cases, spirochetes are readily visible on a routine blood smear prepared with Wright or Giemsa stain. Thick or thin blood smears, such as those prepared for malaria evaluation, also are satisfactory. The organisms are seen within the plasma spaces between blood cells or may overlie the blood cells. Several organisms per high-power field typically are visible in smears from febrile patients with relapsing fever. Blood specimens for the smears should be obtained as the temperature curve swings up, and repeated samples may be required before a positive result is observed, because sensitivity approaches only 70%. Spirochetes also may be visible in wet mounts with the use of phase contrast microscopy. Cultures, although the most sensitive diagnostic method available, require a special medium and do not yield rapid results and so are not commonly performed. Genus-specific PCR testing has now been successfully used and may be higher in sensitivity than either serology or blood smear, especially in the acute phase of disease. Serologic testing offered by the CDC can be accessed through local and state health departments. Nonspecific laboratory findings may include mildly increased bilirubin and liver function levels, thrombocytopenia, and elevated erythrocyte sedimentation rate.

**Differential Considerations**

On initial presentation, the differential diagnosis is extensive; however, it narrows with the occurrence of relapse. A history of possible soft tick exposure together with recurrent fever should suggest the diagnosis. Other conditions that initially may be considered include malaria, typhus, dengue, yellow fever, Colorado tick fever, and tularemia. Careful examination of blood smears, together with clinical data and other laboratory tests, will aid in making the correct diagnosis.

**Management**

Relapsing fever is effectively treated with tetracycline or erythromycin. Tetracycline should be avoided in children younger than 8 years and in pregnant women. Tetracycline or erythromycin should be given in an oral dose of 500 mg for 7 days; single-dose therapy is also effective. Other treatment regimens, including doxycycline and chloramphenicol, have been recommended. Treatment with penicillin G has been associated with an increased rate of relapse. Success with ceftriaxone has been reported in a patient with relapsing fever that did not respond to penicillin. Prophylaxis with doxycycline for tick-borne relapsing fever in exposed subjects in high-risk infested areas has been shown to be effective.

As many as one third of patients will experience a Jarisch-Herxheimer–type reaction during treatment with antibiotics. The reaction can be severe, especially with louse-borne relapsing fever. This phenomenon may be related to release of high levels of cytokine intermediaries or endogenous opioids. Approximately 4 hours after antibiotic treatment and coinciding with the clearance of spirochetes from the blood, the patient usually experiences an increase in temperature and severe rigors, accompanied by a drop in leukocyte and platelet counts and onset of hypotension. Anticipation of this reaction is crucial because intravenous volume expansion with saline solution may be required to maintain the blood pressure; the reaction can be more threatening than the disease itself. Mepetazinol, an opioid antagonist with agonist properties, has been proposed for use in treatment of this reaction.

Prognosis is good in treated patients with relapsing fever, with approximately 95% achieving complete recovery. Bad prognostic signs include the presence of jaundice, high spirochete counts in the blood, and hypotension. Transplacental transmission can occur in infected pregnant women. Perinatal death of the fetus or infant and spontaneous abortions occur in nearly 50% of the cases in pregnant women. Death is rare in tick-borne relapsing fever and is limited to infants and the elderly.

**TULAREMIA**

**Perspective**

Tularemia was first characterized in 1837 by Soken, who described a febrile illness with generalized lymphadenopathy in people who had eaten infected rabbit meat. In 1912, McCoy first isolated *Bacterium tularense*, now known as *Francisella tularensis*, from rodents in Tulare County, California, giving rise to the name of the disease. Edward Francis, for whom the genus *Francisella* was later named, contributed much to the understanding of the bacteriology and epidemiology.

Tularemia occurs worldwide and is endemic between 30 and 71 degrees north latitude. The incidence of tularemia is low. There were 247 reported cases of tularemia in the United States between 2004 and 2005, although it is not a notifiable disease in all states. Tularemia has been seen in every state but is most common in the southwest central region (Arkansas, Louisiana, Oklahoma, Texas, and Mississippi). Fifty-six percent of reported cases have come collectively from Missouri, Oklahoma, South Dakota, and Arkansas. It is more common in men than in women. Persons at increased risk for infection include hunters, trappers, butchers, agricultural
workers, campers, shepherders, mink farmers, and laboratory workers.\textsuperscript{34,55}

Ticks, lagomorphs (hares, rabbits), and rodents (mice, rats) are believed to be the most important sources of transmission to humans; however, the organism has been recovered from animals of more than 100 different species with significant epidemics linked to contact with a variety of them, including domestic cats.\textsuperscript{52,58} A large number of commercially distributed prairie dogs from Texas died from tularemia in 2002.\textsuperscript{37} The ticks most commonly involved in transmission in the United States are the deer tick (\textit{I. scapularis}), the Lone Star tick (\textit{A. americanum}), and the dog tick (\textit{D. variabilis}), all of which have been associated with other tick-borne illnesses. Whereas mosquitoes are major vectors in many European countries,\textsuperscript{58,59} horse fly and deer fly bites have been implicated in endemic situations in the United States.\textsuperscript{90}

Transmission to humans most commonly occurs through tick bites or handling infected animals. It also can occur with ingestion of infected food or water, with inhalation of dust or water aerosol, and through insect bites.\textsuperscript{58,60} Nonimmune laboratory workers who work with\textit{F. tularensis} can acquire the disease. Person-to-person transmission is rare. Tularemia has a bimodal prevalence in the United States, with an increased incidence in May to August associated with tick-borne transmission and a December to January peak associated with hunting and skinning of infected mammals (primarily rabbits).\textit{Francisella tularensis} has been found to coexist in reservoir populations harboring the agent responsible for Lyme disease.\textsuperscript{61}

Eleven cases of pneumonic tularemia, found to be from aerosolization of contaminated vegetation clippings, were discovered in Martha’s Vineyard.\textsuperscript{62} Outside of the United States, tularemia has been confirmed in hundreds of cases in Kosovo, through rodent contamination of food. In addition, Sweden has reported a high number of cases, usually associated with aquatic environments and mosquitoes.\textsuperscript{52,59,63}

**Principles of Disease**

\textit{Francisella tularensis} is a small pleomorphic gram-negative coccobacillus and is a facultative pathogen of macrophages, neutrophils, and nonphagocytic cells such as hepatocytes and alveolar epithelial cells.\textsuperscript{84} Two serologically identical types of \textit{F. tularensis} organisms are responsible for human disease and can be distinguished from each other on the basis of geographic distribution, fermentation reactions, and virulence. Jellison type A (\textit{F. tularensis} biovar tularenisis), the predominant biovar in North America, is associated with ticks and rabbits and causes severe disease in humans. Strain B (\textit{F. tularensis} biovar holarctica) occurs in Asia, Europe, and, to a minor extent, North America; it is associated with rodents and causes milder disease in humans.\textsuperscript{84}

Tularemia manifests in different ways, depending on the portal of entry of the organism. The primary route of infection by \textit{F. tularensis} is through the skin. Entry can occur through hair follicles or through small cuts and abrasions that may be contaminated by exposure to an infected animal; tick exposure can also introduce the bacteria.\textsuperscript{84} Because the bacterium has not been isolated from the salivary glands of ticks, it is thought that they transmit the organism through their feces.\textsuperscript{51} Scratching after a tick bite introduces the infected feces into the skin. Inhalation or ingestion of the organism or transmission through the conjunctivae also can cause infection. The incubation period is approximately 2 to 6 days, depending on the size of the inoculum.

After penetration of the skin or epithelial membrane, the organism usually spreads to the regional lymph nodes. An erythematous tender papule develops at the primary infection site, followed by inflammation and skin ulceration. The regional nodes enlarge, necrose, and may rupture. The necrotic, purulent, painful lymph node is termed a bubo. In the ulceroglandular form of the infection, the organism may not spread further than the regional lymph nodes. If the inoculum is sufficiently large or the host defenses are inadequate, bacteremia ensues, with dissemination to phagocytic cells of the reticuloendothelial system.

Pulmonary tularemia may result from inhalation of small-particle aerosols containing \textit{F. tularensis} or may be secondary to hematogenous dissemination. Small areas of localized pneumonitis most commonly are seen, although chest radiographic findings are nonspecific; lobar consolidation or abscess formation is rare. Oculoglandular tularemia occurs when the conjunctiva becomes infected from contact with material from an ulcer or a contaminated finger. Typhoidal tularemia follows systemic spread of \textit{F. tularensis} from the oropharynx and probably the gastrointestinal tract when a large inoculum is swallowed.

**Clinical Features**

Tularemia has six clinical presentations, depending on whether disease is localized to an entry site and its regional lymph nodes—ulceroglandular, glandular, oculoglandular, and oropharyngeal forms—or is more invasive and generalized—typhoidal and pulmonary forms.

**Ulcerglandular** tularemia is the most common form of the disease (accounting for approximately 80% of the cases). Typically, a skin lesion on an extremity at the site of primary inoculation begins as an erythematous papule, which then ulcerates 2 to 3 days later.\textsuperscript{34} The ulcer is slow to heal and often is still present when the subsequent regional lymphadenopathy and fever develop. The distribution of the regional adenopathy reflects the primary entry site; patients with tick-borne tularemia usually have inguinal or femoral adenopathy, whereas those who acquire rabbit-associated tularemia have axillary or epitrochlear nodal involvement. Generalized lymphadenopathy also may be seen. Occasionally, nodes suppurate and drain.\textsuperscript{34}

**Glandular** tularemia, the second most common form, is characterized by the development of lymphadenopathy (usually cervical) without an associated skin ulcer. \textit{Oropharyngeal} tularemia is seen in 1 to 2% of cases and is characterized by unilateral conjunctivitis with regional adenopathy involving preauricular lymph nodes. \textit{Oropharyngeal} tularemia manifests as severe exudative pharyngitis with associated cervical lymphadenitis. It has been known to cause acute glaucoma.\textsuperscript{32,65}

**Typhoidal** tularemia is a systemic form of the disease in which no obvious entry site can be found; it occurs in approximately 10% of cases. Only 10 to 50 organisms are required to induce disease; incubation time is 2 to 10 days.\textsuperscript{58} Symptoms and signs may include fever, chills, constipation or diarrhea, abdominal pain, and weight loss. A 30 to 60% case-fatality rate is associated with untreated typhoidal tularemia.\textsuperscript{66}

**Pulmonary** tularemia is common and has symptoms similar to those of other bacterial pneumonias: fever and chills, cough (usually nonproductive), substernal burning, dyspnea, malaise, and prostration. It may result from either direct inhalation of aerosolized organisms or bacteremic spread from another site.

Uncommon complications of tularemia include pericarditis, meningitis, endocarditis, peritonitis, appendicitis, peripancreatitis, and osteomyelitis.\textsuperscript{34} Guillain-Barré syndrome associated with tularemia also has been reported.\textsuperscript{66}

Tularemia is one of the most widely studied diseases with respect to potential biologic warfare. The United States devel-
opened an aerosolized form in the 1950s, and the Japanese allegedly contaminated prisoners with the disease in the 1930s. It was removed from the national list of notifiable diseases in 1995 but then was reinstated in view of the heightened biologic weapons threat. It is now classified by the CDC as one of the six category A critical biologic diseases. An aerosolized form of the bacterium would be the most likely delivery mechanism used in biologic warfare. With release of aerosolized particles, disease would manifest clinically as acute fever, progressive pneumonia, pleuritis, and hilar lymphadenopathy, beginning as early as 3 to 5 days after delivery. Only approximately 55% of emergency departments have been adequately educated on the recognition of and preparedness for tularemia.

Diagnostic Strategies

Diagnosis of tularemia is based on clinical findings and serologic testing. Antibody titers begin to rise approximately 7 to 10 days after exposure and peak in 3 to 4 weeks. In a patient with a clinical presentation suggesting tularemia, an antibody titer of 1:160 or greater in a single specimen is diagnostic. Confirmatory evidence is provided by a fourfold or greater rise in titer in a second sample obtained 2 weeks later. Unfortunately, titers of IgG and IgM can continue to be high for up to 10 years, and cell-mediated immunity can be maintained for up to 25 years. Rapid testing with PCR assay is available. A rapid point-of-care test using an immunochromatographic approach is currently being evaluated.

Aspiration of affected lymph nodes for culture is not routinely recommended because of the associated risk to laboratory personnel. If tularemia is suspected, the laboratory should be alerted so that appropriate precautions can be taken in specimen handling and so that enriched culture medium can be used.

Management

Isolation of patients with tularemia is not required. Streptomycin is the drug of choice for treatment of all forms of tularemia. When given intramuscularly in a dose of 30 to 40 mg/kg per day in two divided doses every 12 hours, streptomycin usually produces symptomatic improvement and resolution of fever in 1 to 2 days. After the third treatment day, one half of the dose is given for a total course of 7 to 14 days. With this regimen, relapses are unusual.

Ulcers and tender lymph nodes usually heal within 7 to 10 days; however, enlarged nodes occasionally develop into fluctuant sterile buboes, requiring incision and drainage after completion of the course of antibiotics. Gentamicin also is effective for treatment (3 to 5 mg/kg/day for 10 to 14 days). Tetracycline and chloramphenicol are effective; however, the risk of relapse is greater than that associated with the aminoglycosides. Imipenem-cilastatin, an antibiotic without nephrotoxicity, has been used successfully to treat pulmonary tularemia in a patient with acute renal failure. Ceftriaxone is not effective against F. tularensis infections. Prophylaxis for possible exposure requires doxycycline, 100 mg twice a day for 14 days. Doxycycline or ciprofloxacin prophylaxis is recommended for a large biologic attack. An effective live vaccine strain has been available for vaccination against tularemia for nearly 50 years, but licensure approval has been delayed owing to a lack of understanding of the vaccine’s mechanism of action and attenuation. Because of recent interest in biologic warfare, research on tularemia vaccines has resurfaced.

The overall mortality rate in untreated tularemia ranges from approximately 5% to 30%; the higher figure is associated with severe disease or significant pulmonic involvement. With appropriate antibiotic treatment, death is rare (mortality rate of less than 1%).

ROCKY MOUNTAIN SPOTTED FEVER

Perspective

RMSF is an acute, febrile, systemic tick-borne illness caused by Rickettsia rickettsii. There are 11 other rickettsial species that cause human disease in other parts of the world. RMSF is found in North, South, and Central America. The number of reported cases in the United States more than tripled between 2001 and 2005, especially in suburban areas. RMSF ranges in clinical severity from mild or even subclinical illness to a fulminant disease with vascular collapse and death within several days of onset. It is the only rickettsiosis still associated with significant mortality, causing approximately 40 deaths in the United States each year, with a mortality rate ranging from 3 to 5% despite appropriate treatment. Before tetracycline and chloramphenicol were available, death occurred in as many as 30% of cases in the 1930s. The age-specific incidence is highest in children younger than 10 years, and case-fatality rates are highest in persons older than 60 years. RMSF is a nationally reportable disease, with all cases to be registered with the respective state department.

The recorded history of RMSF suggests that the disease was present at least before the white settlement of western North America, in afflicted Native American inhabitants of wooded Rocky Mountain regions. Early terms used to name the disease included “tick fever” and “black measles.” In 1899, RMSF was described as “an acute, endemic, noncontagious but probably infectious, febrile disease, characterized by a continuous moderately high fever, severe arthritic and muscle pains, and a profuse petechial or purpuric eruption in the skin, appearing first on the ankles, wrists, and forehead, but rapidly spreading to all parts of the body.” In 1906, the causative organism, Rickettsia rickettsii, was identified by Howard T. Ricketts, who also described the importance of the tick vector in transmission to humans.

Although RMSF was first described in Montana and Idaho, it is now relatively rare in the Rocky Mountain states. Endemic in all 48 contiguous states except Maine, the disease continues to be most prevalent in the southeastern United States. RMSF has been reported in Canada, Central America, Mexico, and South America but never outside the Western Hemisphere. In 1987, four cases of RMSF were reported among residents of the Bronx in New York City; none of the affected persons had recently traveled to an area known for endemic disease—raising the possibility that other urban foci of RMSF may exist.

RMSF also tends to be focally endemic, with clustering of cases within a larger endemic area that may correspond to “islands” of infected ticks. These areas, ecologically distinct from surrounding areas, may be ideally suited to ticks; they usually consist of wild open fields, deciduous forests with thick ground cover and poor water drainage, or uncultivated areas. In areas with frequent occurrence of RMSF (Oklahoma, North and South Carolina, Tennessee, and Pennsylvania), an infectivity rate of 2 to 15% of the tick population has been reported. North Carolina and Oklahoma carry the highest incidence rates (35% of all cases) for RMSF.

Rickettsia rickettsii organisms are obligate intracellular bacteria that often occur in pairs and possess a cell wall similar in structure and chemical composition to that of gram-negative bacteria. R. rickettsii contain both RNA and DNA and, in contrast with other rickettsial organisms, can invade the nucleus as well as the cytoplasm.
Principles of Disease

After introduction of *R. rickettsii* into the host by the tick vector, the organisms invade and multiply in the vascular endothelial cells. They then enter deeper areas of the vessel walls and infect vascular smooth muscle. Rickettsial organisms move from cell to cell by actin-based motility. Damage to endothelial cells not only exposes subendothelial but also releases tissue plasminogen activator and von Willebrand factor, thereby causing microhemorrhage, microthrombus formation, and increased vascular permeability. In addition, antibody forms, with antigen activating the complement system (type III immune response), and a cellular response is recruited.

These widespread vascular lesions form the basis for most of the clinical features associated with RMSF. Hypotension, edema, and increased extravascular fluid space result from the increased small-vessel permeability. The early rash results from the vasculitis and the associated changes in permeability; later petechial and hemorrhagic lesions are secondary to the vasculitis and thrombocytopenia. Microinfarcts and focal lesions develop in various organs, including the brain, heart, lungs, kidneys, adrenal glands, liver, and spleen. Rickettsial encephalitis and diffuse microinfarcts are usual features of central nervous system involvement. An interstitial pneumonitis caused by direct lung invasion by the organism may occur, and acute respiratory distress syndrome (ARDS) can ensue. Acute renal failure and hypovolemic shock, the primary causes of death, can occur as early as the second week of illness.

Clinical Features

Children from 5 to 9 years of age are the most common victims of RMSF. Two thirds of all cases are in children younger than 15 years. More than 90% present with a fever and rash. A history of tick bite or presence in possible tick-infested areas is elicited in 60 to 70% of all patients with RMSF, although only 49% of the pediatric population reports a tick bite. The incubation period ranges from 2 to 14 days, with a mean of 7 days. A short incubation period may indicate a more serious infection.

Onset of symptoms usually is abrupt but is gradual in approximately one third of patients. Early symptoms are nonspecific and similar to those of many acute infectious diseases, making early diagnosis very difficult. “Typical” patients experience sudden onset of fever, severe headache, myalgias, prostration, nausea, and vomiting. Tenderness may be noted in large muscle groups (Table 132-4). As many as 80% of patients may have gastrointestinal symptoms, secondary to myositis of the abdominal wall. Fever (temperature usually higher than 102°F) is nearly always present during the first 2 to 3 days of illness and may precede other signs by 1 week or more. Occasionally, the onset of illness is mild, with lethargy, headache, anorexia, and low-grade fever; these patients may remain ambulatory. Although the triad of fever, rash, and tick exposure traditionally has been seen in only approximately 3 to 18% of cases, newer data show that it is found in up to 45% of children with the disease. An extreme complication of RMSF is gangrene, which probably is induced by small-vessel occlusion.

Cutaneous Manifestations

Vasculitis secondary to rickettsial invasion of vascular endothelial cells causes the rash commonly associated with RMSF; however, the rash reportedly is absent in 4 to 16% of laboratory-confirmed cases, referred to as “Rocky Mountain spotless fever.” In addition, the rash may go unnoticed in dark-skinned patients. It usually appears on the third to fifth febrile day but may precede other signs by 1 week or more. Occasionally, the onset of illness is mild, with lethargy, headache, anorexia, and low-grade fever; these patients may remain ambulatory. Although the triad of fever, rash, and tick exposure traditionally has been seen in only approximately 3 to 18% of cases, newer data show that it is found in up to 45% of children with the disease. An extreme complication of RMSF is gangrene, which probably is induced by small-vessel occlusion.

</table>

The rash of RMSF typically begins as 1- to 5-mm blanchable pink to bright red discrete macules that may be pruritic (Fig. 132-7). At this initial stage, the lesions fade when pressure is applied and are not palpable. A warm compress applied to the area enhances the rash. After 6 to 12 hours, the rash spreads centripetally. After 2 to 3 days, the rash becomes maculopapular and changes to a deeper red; at this stage, skin changes can be appreciated on light palpation. By approximately the fourth day, the rash becomes petechial and no longer fades with applied pressure. Applying tourniquets for several minutes or taking the blood pressure may cause additional petechiae to form distal to the site of occlusion (Rumpel-Leede phenomenon). Occasionally, the lesions coalesce to form large ecchymotic areas that may slough and form indolent ulcers (Fig. 132-8).

Prompt institution of specific therapy can cause the initial nonfixed lesions to disappear rapidly, unlike the later fixed lesions. Patients who have had the typical rash may exhibit brownish discolorations at the site during the convalescent period.

**Cardiopulmonary Manifestations**

Echocardiographic evidence of decreased left ventricular contractility secondary to myocarditis commonly is seen and often is detectable even before clinical signs of RMSF appear. Clinical manifestations of left ventricular dysfunction are uncommon, however, and hypotension and pulmonary edema, when present, usually have noncardiogenic causes. Chest radiographs may demonstrate cardiac enlargement. Electrocardiographic changes include low-voltage, nonspecific ST-T changes, first-degree AV block, dysrhythmias (sinus and nodal tachycardia, paroxysmal atrial tachycardia, atrial fibrillation), and left ventricular hypertrophy. Most cardiac abnormalities are transient, but persistent echocardiographic changes have been described. Decreased systolic function, elevated serum cardiac markers, no finding of vascular lesions, and a fourfold rise in antibody titers are consistent with myocarditis from RMSF.90

Interstitial pneumonitis and increased pulmonary capillary permeability may result from infection of the pulmonary capillaries with rickettsiae. Nonproductive cough and dyspnea secondary to pneumonia are sometimes seen on presentation.91 Chest radiographic abnormalities are identified in approximately 25% of patients. These abnormalities include interstitial infiltrates, patchy alveolar infiltrates, pleural effusions, and
cardiomegaly with pulmonary edema. Pulmonary consolidation is rare. In severe cases, progression to noncardiogenic pulmonary edema and ARDS may occur.

Neurologic Manifestations

Neurologic manifestations of RMSF range from mild headache and lethargy to seizures and coma. Acute disseminated encephalomyelitis has been described. Headache, generally severe, is common, occurring in 50 to 90% of cases. Meningismus is present in 16 to 29% of patients. The CSF may be normal or show slight protein elevation and pleocytosis of both lymphocytes and polymorphonuclear cells (usually 8 to 35 cells/mL). CSF glucose level and opening pressure usually are normal. Resolution of eosinophilic meningitis during RMSF after appropriate antibiotic treatment has been reported. Fewer than 40% of patients have a positive CSF finding.

Cerebral thrombovasculitis may cause focal neurologic deficits, which usually are transient. Seizures can occur, especially during the acute phase of the illness. Generalized cerebral dysfunction ranging from lethargy to coma can occur secondary to systemic toxicity (fever, hypotension, hyponatremia) or to vasculitic lesions involving the central nervous system. Coma is a late finding in patients with severe disease and is seen in less than 10% of cases. Some reports have described patients who remain alert but are amnesic for their illness after recovery.

Other reported neurologic manifestations include transient deafness, tremor, rigidity, athetoid movements, paralysis, ataxia, opisthotonos, aphasia, and blindness. Generally, neurologic signs abate without residua; permanent neurologic deficits are rare. Behavioral disturbances and learning disabilities have been reported after recovery from RMSF-associated coma in children.

Diagnostic Strategies

Most immediately available laboratory tests provide little help in diagnosing RMSF. Early in the course of the illness, the diagnosis is based primarily on clinical evidence, so epidemiologic features must be correlated with clinical signs and symptoms. The initial presentation of RMSF is similar to that of many acute febrile infectious diseases, and almost invariably a therapeutic decision must be made on clinical grounds alone, without the luxury of confirmatory laboratory evidence. Abnormalities such as thrombocytopenia and hyponatremia may be detected by routine laboratory tests, but they are nonspecific and unhelpful diagnostically. Up to 30% of patients present with anemia. A definitive diagnosis of RMSF requires positive results on one or more of several tests: serologic study, skin biopsy, or direct isolation and identification of the organism (Box 132-1).

Serology

Rickettsial infection can be confirmed by demonstrating antibody rise in paired sera. Even with the most sensitive serologic tests, however, elevations in antibody titers do not occur until approximately 5 to 7 days after the onset of initial symptoms. Accordingly, serodiagnosis is retrospective. It is achieved by comparing acute serum, which typically yields negative findings, with convalescent serum, which yields positive results for antibodies. The indirect immunofluorescence assay (IFA) generally is considered the reference standard for diagnosis of RMSF and is the test currently used by the CDC and most state public health laboratories. It has a high specificity and sensitivity (94%). IFA can be used to detect either IgG or IgM antibodies. A RMSF latex agglutination test that reportedly gives a turnaround result in less than 24 hours is available in selected laboratories. A recent study showed a 12% seroprevalence, with antibody titers of 1:64 or greater, in the pediatric population in the southeastern and south central regions of the United States. Accordingly, clinical correlation with titers in these regions is critical.

Convalescent-stage blood samples are best obtained 2 to 3 weeks after the onset of clinical illness. Antibiotic therapy does not affect the time of appearance of antibodies or their ultimate titer if such treatment is begun several days after the onset of illness. However, if antibiotic therapy is initiated earlier in the course of the illness, the rise in titers can be delayed for 4 weeks or more. Under these circumstances, antibody titers should be tested again at 4 to 6 weeks after the onset of illness.

Skin Biopsy

Identification by immunofluorescent assay and immunoperoxidase staining of \textit{R. rickettsii} in biopsy specimens of the skin rash from patients with suspected RMSF are the best rapid diagnostic tests currently available. In experienced laboratories, the diagnosis of RMSF can be confirmed as soon as 4 hours after the specimen is obtained. The organisms can be detected as early as day 3 of clinical illness and as late as day 10. Unfortunately, this technique can be used only when a rash is visible for accurate localization of the biopsy site. Biopsy specimens generally are obtained with a 3-mm punch in the

---

**BOX 132-1  DIAGNOSTIC CRITERIA FOR ROCKY MOUNTAIN SPOTTED FEVER**

**Laboratory Criteria**

- Serologic evidence of a significant change in serum antibody titer reactive with \textit{Rickettsia rickettsii} antigens between paired serum specimens, as measured by a standardized assay conducted in a commercial, state, or reference laboratory.
- Demonstration of \textit{R. rickettsii} antigen in a clinical specimen by immunohistochemical methods.
- Detection of \textit{R. rickettsii} DNA in a clinical specimen by the polymerase chain reaction (PCR) assay.
- Isolation of \textit{R. rickettsii} from a clinical specimen in cell culture.

For confirmed cases, a significant change in titer must be determined by the testing laboratory; examples of commonly used measures of significant change include, but are not limited to, a fourfold or greater change in antibody titer as determined by indirect immunofluorescent antibody (IFA) assay or an equivalent change in optical density measured by enzyme-linked immunosorbent assay (ELISA).

**Case Classification (CDC Case Definition, 2004)**

- **Confirmed:** The patient has a clinically compatible illness that is laboratory confirmed.
- **Probable:** The patient has a clinically compatible illness and serologic evidence of antibody reactive with \textit{R. rickettsii} in a single serum sample at a titer considered indicative of current or past infection (cutoff titers are determined by individual laboratories).

center of the skin lesion. Immunofluorescent demonstration of rickettsiae in frozen sections of skin biopsies has a sensitivity of 70%. Results of immunohistochemical staining of tissues at autopsy were positive in all fatal cases in one study, whereas IFA results were negative in the majority of cases. Failure to obtain a biopsy specimen of a rickettsial cutaneous lesion or failure to obtain sections through its center is associated with false-negative results. Treatment with antirickettsial drugs for 24 hours does not appreciably alter the sensitivity of the test; however, after 48 hours, rickettsiae are substantially reduced in numbers.

Isolation of Organism

For most pathogenic infections, the standard diagnostic criterion is isolation and identification of the etiologic organism from the patient’s blood or tissues. This is seldom attempted in rickettsioses, however, because the isolation procedures are time-consuming, expensive, and hazardous to laboratory personnel. In addition, primary isolation of rickettsiae by inoculation in the yolk sac of a chick embryo usually fails because of the small number of organisms in the patient’s blood.

Differential Considerations

Delayed diagnosis or misdiagnosis is the principal reason for the significant mortality associated with RMSF. Clinical diagnosis is difficult, especially early in the course of the illness, because of the nonspecific presentation. To prevent avoidable deaths, a diagnosis of RMSF must be considered in any patient with an unexplained febrile illness (with or without a rash and headache), even in the absence of a history of tick bite or travel to an area known to be endemic for the disease. An atypical presentation or manifestation of RMSF also must be considered during the differential diagnosis, including (1) absence of a rash (“Rocky Mountain spotted fever”) or late appearance of a rash, (2) predominant gastrointestinal features or abdominal pain suggestive of an acute condition in the abdomen, (3) cough and pulmonary congestion suggestive of pneumonia, and (4) meningismus suggestive of viral meningitis. A presumptive diagnosis must be made and specific therapy initiated well before specific confirmatory laboratory values are available.

A wide variety of other infections with similar exanthems can be confused with RMSF. The most common include meningococcal infection, measles (rubeola) and atypical measles, gonococcal, infectious mononucleosis, toxic shock syndrome, and enteroviral infections. Less common diseases include dengue, leptospirosis, murine typhus, and epidemic typhus.

Management

Treatment of RMSF consists of antibiotic therapy, supportive care, and possibly administration of steroids. An understanding of the underlying pathophysiologic changes and an appreciation of the systemic complications that can occur in the patient afflicted with RMSF are necessary for the formulation of a balanced therapeutic regimen. The course of the disease can be complicated by circulatory collapse, coma, renal failure, and electrolyte imbalances. Although often absent in the mildly ill patient, in whom antibiotic therapy alone usually suffices, these complications should be anticipated in the seriously ill patient, especially if first seen late in the disease course.

The most important factor contributing to the persistent case-fatality rate of 5% is delayed administration of specific antibiotic therapy. Without appropriate treatment, the fatality rate rises to 25%. For a select group of early-stage, mildly ill patients, outpatient therapy with oral antibiotics can be successful if the patient is reliable and close follow-up observation is arranged. More severely ill patients in whom the diagnosis is uncertain should be hospitalized for administration of intravenous antibiotics.

Antibiotics

Antibiotic therapy is most effective when initiated during the early stages of disease, coincident with the initial appearance of the rash. Although data from randomized clinical trials regarding antibiotic selection for RMSF are lacking, doxycycline is still widely regarded as the therapeutic agent of choice for most patients. Chloramphenicol should be considered only for patients in whom the tetracyclines have caused significant adverse events and for pregnant women (except those who are near term). The recommended doses of doxycycline and chloramphenicol are summarized in Table 132-5.

Although previous treatment guidelines recommended avoiding doxycycline in children younger than 8 years of age, the American Academy of Pediatrics and the CDC currently recommend doxycycline therapy as the agent of choice for treatment of RMSF in children of all ages. The risk of cosmetically perceptible tooth staining appears to be small for a single course of treatment and is subordinate to the potential lethality of this illness.

The effectiveness of therapy depends on both the duration of therapy and the interval between the onset of illness and the initiation of therapy. Treatment should begin as early as possible and continue for 7 to 10 days or until the patient is afebrile for 2 to 5 days. Patients who are clinically ill should be hospitalized for parenteral antibiotic treatment. Response to treatment, as manifested by decreasing fever and subsiding rash, generally occurs 36 to 48 hours after beginning antibiotic therapy. Resistance to chloramphenicol or the tetracyclines has not been reported. Penicillin, erythromycin, cephalosporins, aminoglycosides, clindamycin, and sulfonamides are ineffective against RMSF. In fact, empirical use of these agents for presumed bacterial infections may potentially permit progression of the illness.

Occasionally, secondary bacterial infection from the RMSF rash may occur. Although sulfonamides have recently become a mainstay for empirical treatment of MRSA for skin infections, the use of these agents should be avoided in RMSF patients, since their mechanism of inhibiting para-aminobenzoic acid may worsen the primary RMSF infection. The role

<sup>1</sup>Continued treatment at least 3 days after fever subsides or until unequivocal clinical improvement is seen; minimum course, 5 to 7 days.

<sup>*</sup>Doxycycline should not be given to pregnant women.

<sup>‡</sup>Chloramphenicol should not be given to patients with thrombocytopenia; maximum of 1 g/day for children.

of the new quinolones as potential replacements for doxycycline and chloramphenicol in the treatment of RMSF is as yet unproved. At present, no vaccine is available for RMSF.

Supportive Care

Major complications of RMSF, such as shock, congestive heart failure, disseminated intravascular coagulation, and ARDS, should be anticipated and standard supportive measures instituted when appropriate. Circulatory collapse is common in patients with severe illness and is a major contributor to morbidity and mortality in RMSF. Hypotension unresponsive to fluid administration may require the use of vasopressors such as dopamine. In the critically ill patient with widespread vasculitis, however, a delicate balance exists between maintenance of effective circulating volume and excessive leakage of fluids into the tissues, including the lungs and brain. Under these circumstances, the excessive administration of intravenous fluids can be catastrophic. Isolation of the patient is unnecessary unless the diagnosis is still uncertain and other highly communicable illnesses such as meningococccemia or measles have not been excluded.

Corticosteroids

The use of steroids in RMSF is controversial and is not routinely recommended. However, these agents should be considered for severe cases of RMSF complicated by extensive vasculitis, encephalitis, and cerebral edema. In these critically ill patients, short-term, high-dosage steroid therapy is recommended, along with concomitant specific antibiotic therapy.

■ Q FEVER

Perspective

Q fever was first described in 1937 in Australia as an occupational disease of abattoir workers and dairy farmers. Cattle, sheep, goats, and ticks are the primary reservoirs of the causative rickettsia, *Coxiella burnetii*, but many other species may be infected. The disease is endemic worldwide, although it is rare in Scandinavian countries. The *Q* fever rickettsiae are extremely resistant to desiccation and to physical and chemical agents and can survive for long periods in an inanimate environment.

Principles of Disease

*Coxiella burnetii* is extremely infectious for humans and animals; a single inhaled organism is sufficient to initiate infection in guinea pigs and probably in humans as well. Consequently, it is classified as a category B biologic warfare agent by the CDC and has been a nationally notifiable disease since 1999. This organism’s infectivity and estimated casualty rate have been judged to be comparable with those of anthrax. Humans most commonly are infected by inhalation of aerosolized particles from contaminated environments. Patients with *Q* fever rarely can recall a history of tick bite. The Rocky Mountain wood tick, *Dermacentor andersoni*, is the only currently known tick vector.

Clinical Features

The incubation period of *Q* fever ranges from 14 to 39 days, with an average of 20 days. Up to 60% of initial infections are asymptomatic. The acute form of the disease includes clinical manifestations such as severe retrobulbar headache, a fever with temperatures to 40°C or higher, shaking chills, general malaise, myalgia, and chest pain. Although *Q* fever is widely regarded as primarily a respiratory disease, the reported incidence of pulmonary involvement varies, ranging from zero to 90%. The reasons for this variation are unclear, but explanations include geographic strain variation, plasmin that may regulate virulence, and the source, route, and dose of the agent. Hepatic involvement may be common, but liver dysfunction is usually minimal. Osteomyelitis in children, acute renal failure, and lymphocytic meningitis secondary to *C. burnetii* have been described.

*Q* fever also may be a chronic infection, with or without an antecedent acute episode. Clinical syndromes with the chronic form of the disease include granulomatous hepatitis and culture-negative endocarditis. Endocarditis has been documented in up to 68% of patients with chronic *Q* fever, and the mortality rate for this group approaches 25%. *Q* fever accounts for 3 to 5% of all cases of endocarditis. Most patients with *Q* fever in whom endocarditis develops have a history of valvular heart disease, particularly affecting the aortic valve. These patients should be especially cognizant of the potential hazards of *Q* fever infection and should be restricted from certain at-risk occupational settings. Patients with aneurysms and vascular grafts also are at risk.

Human fetal demise and deaths have been attributed to *C. burnetii* infection. Persons infected with human immunodeficiency virus (HIV) are at increased risk for contracting *Q* fever.

Diagnostic Strategies

The diagnosis of *Q* fever should be suspected in any patient with a severe febrile illness without obvious cause, especially someone who has had recent contact with sheep, cattle, goats, or animal by-products. Because of the laboratory hazards associated with cultivation of *Q* fever rickettsiae, isolation of *C. burnetii* is not recommended for routine diagnosis. Rather, serologic studies such as IFA and ELISA are the preferred diagnostic tests, but the results are not identifiable until 2 to 3 weeks after the onset of illness.

Coxiella burnetii displays an antigenic phase variation: In patients with acute *Q* fever, phase II antibodies dominate the humoral immune response and are detectable by the second week of illness, whereas phase I antibodies are prominent only in patients with chronic *Q* fever. Confirmation of a *Q* fever case requires (1) a fourfold increase in IgG titers between acute and convalescent samples or the presence of IgM phase II antibodies, (2) a positive PCR test result, (3) culture of *C. burnetii* from a clinical specimen, or (4) positive immunostaining of the organism in tissue. Measurement of IgA and IgG together has been useful in diagnosing endocarditis. The finding of granulomatous changes on bone marrow biopsy can be characteristic of *Q* fever in patients with osteomyelitis.

Management

Treatment of uncomplicated acute *Q* fever is accomplished with doxycycline (200 mg once daily for 2 to 3 weeks). Acute disease with concomitant valvular heart disease is treated with doxycycline (200 mg once daily) plus hydroxychloroquine (600 mg once daily) for 1 year. Chronic sufferers should receive the same regimen for 1.5 to 3 years. Combination therapy with both doxycycline and hydroxychloroquine has been shown to be effective for treatment of endocarditis in HIV-infected patients. In mass casualty situations, prophylaxis is accomplished with 5 to 7 days of doxycycline. Most acute *Q* fever infections resolve without treatment, but the risk of
chronic infection makes treatment advisable. The mortality rate is less than 1% in untreated patients and lower still in those treated with antibiotics. The prognosis is worse in those patients with protracted illness and hepatic involvement or endocarditis. Inactivated whole-cell vaccines for Q fever have proved effective for as long as 5 years. Vaccination can afford considerable protection to slaughterhouse and dairy workers and others at risk.

### THE EHRLICHIOSES

#### Perspective

There are currently two major forms of human ehrlichiosis in the United States: human monocytic ehrlichiosis (HME) and human granulocytic anaplasmosis (HGA), caused by the bacteria *Ehrlichia chaffeensis* and *Anaplasma phagocytophilum*, respectively. In 2001, restructurings of the *Ehrlichia* phylogenetic branches placed the previously known bacteria of human granulocytic ehrlichiosis (HGE) into the genus *Anaplasma*—hence the revised name. Both genera, *Ehrlichia* and *Anaplasma*, are now considered to be in the tribe Ehrlichiae, family Anaplasmataceae, but are still collectively referred to as being in the group of diseases called ehrlichioses. Before 1986, *Ehrlichia sennetsu* was the only member of the genus of these organisms thought to infect humans, having been isolated in Japan in 1954 as the causative agent of sennetsu fever, a monoclonus-cel-like illness. A third species, *Ehrlichia ewingii*, has been shown to cause human disease in the United States. HME was discovered in 1986 and HGA (previously HGE) in 1994. Both are identified as emerging diseases by the CDC and are nationally notifiable diseases, reportable through the appropriate state departments.

More than 1220 U.S. ehrlichiosis cases were reported between 1986 and 1997. From 1999 through 2001, the CDC collected a mean number of 81 and 190 cases, respectively, for HME and HGA. Seroprevalence rates up to 15% for *E. chaffeensis* in children in the southeast and south central states and 3 to 15% for *A. phagocytophilum* in adults in New York and Wisconsin strongly suggest that these diseases are highly underdiagnosed or underreported (or both). Both diseases peak around June through August. High-risk populations are similar to those at high risk for Lyme disease, including those living in endemic areas or with frequent contact with wildlife or rural, wooded areas. A unique case series of ehrlichiosis in a group of golfers showed that those who spent more time in the rough and wooded areas searching for lost balls were at higher risk. HME has been reported predominantly in the south central and southeastern United States; HGA mostly is found in the upper Midwest, New England, parts of the mid-Atlantic states, northern California, and many parts of Europe.

#### Principles of Disease

The causative agents in the ehrlichioses are gram-negative, obligate intracellular rickettsia-like coccobacilli. Transmitted from the midgut and salivary glands of their tick vectors, these organisms reside in specific circulating leukocytes in human and other mammalian hosts. Reservoirs include the white-tailed deer and the white-footed mouse. *E. canis* is the common pathogenic species in dogs. The species *E. equi* has been isolated in California elk. HME, transmitted by the Lone Star tick, *Amblyomma americanum*, is caused by the organism *E. chaffeensis* (named for Fort Chaffee, Arkansas), which invades monocytes. *E. chaffeensis* has been isolated from *I. pacificus* ticks in California. *A. phagocytophilum* invades neutrophils (granulocytes), causing HGA, and in the United States is transmitted by the black-legged tick, *I. scapularis*, and its West Coast counterpart, the western black-legged tick, *I. pacificus*. Deer, elk, and wild rodents are the main reservoirs for *Anaplasma*. Both ticks also are the vectors for Lyme disease. *A. phagocytophilum* has now been detected in significant numbers in various *Ixodes* human tick species in mainland Portugal, Italy, and Japan. Two cases of HGA in Italy have been reported.

#### Clinical Features

The clinical presentations of HME and HGA are similar, and for case management, it is not necessary to differentiate between the two illnesses. The average time to onset of symptoms (for HME) from tick discovery is 9 days but ranges from 0 to 34 days. More than 90% of patients with HME report a history of tick bite or tick exposure. Ehrlichiosis characteristically manifests with abrupt onset of fever, headache, myalgia, and shaking chills. Other, less frequent manifestations include nausea, vomiting, diarrhea, abdominal pain, cough, and confusion. Leukopenia, thrombocytopenia, and elevated liver function test values can be seen in 50 to 90% of patients.

Rashes occur in approximately one third of patients with HME but in only 2 to 11% of those with HGA. In a small series of pediatric patients (average age, 7.4 years) with HME, a rash rate of 67% was found. A majority of these patients suffered permanent cognitive or other neurologic damage.

Ehrlichiosis (HME) also has been associated with optic neuritis. ARDS, meningitis, pancarditis, renal failure, and disseminated intravascular coagulation have been associated with the ehrlichioses. Case-fatality rates vary between studies, but range between 0.5% and 3% for both diseases, with HGA usually reported as the lower of the two. Approximately 45% of patients with HGA require hospitalization, although almost all recover without residual problems.

#### Diagnostic Strategies

For both HME and HGA, the initial diagnosis is based largely on clinical presentation. With most tests, the diagnosis will be retrospective, or results rarely are available immediately. The most common mode of diagnosis is confirmation of acute and convalescent antibodies with IFA. Enzyme immunoassay and confirmatory tests with Western blot have been developed. PCR testing for DNA fragments, although not readily available in most hospitals, probably is most reliable in the acute phase of illness (at 1 week after onset of symptoms). Diagnostic serologic testing is available at the CDC through state health departments.

Laboratory criteria required in the CDC’s 2000 case definition to establish the presence of either HME or HGA include detection of either *E. chaffeensis* or *A. phagocytophilum*, respectively, through the use of the following diagnostic tests: (1) fourfold change in antibody titer to the organism antigen by IFA in paired serum samples, (2) positive result on PCR assay and confirmation of organism-specific DNA, (3) identification of morulae in leukocytes and a positive titer to the organism antigen, (4) immunostaining of organism antigen in a biopsy or autopsy specimen, or (5) culture of the organism from a clinical specimen. A designation of “probable disease” requires a single positive IFA titer, based on cutoff values from the performing laboratory, or the presence of morulae within infected cells. All tests require compatible clinical findings. Most patients with clinical manifestations have IFA titers between 1:160 and 1:1280 at presentation.
Cytopenia and abnormal liver function usually resolve after the acute phase of illness by 14 to 28 days. Microscopic identification of mulberry-like clusters, called morulae, inside leukocytes on peripheral blood smears is helpful, but this finding usually has disappeared after the first week of illness with HGA, especially if the patient has been treated with doxycycline. Cultures take up to 2 weeks to grow the organisms.

Management

Tetracycline, which has been shown to be effective in cases of canine ehrlichiosis, is also effective in cases of human ehrlichiosis. Doxycycline (100 mg twice a day) and tetracycline regimens for 7 to 14 days are curative. Most patients respond rapidly after treatment is begun, and fever subsides within 24 to 48 hours. For pediatric patients, the concern for tooth staining is obvious, although it has been argued that most of this effect is seen only with multiple dosing periods. Rifampin as an alternative has been shown to be effective in children with human ehrlichiosis. Data supporting the use of chloramphenicol are still inconclusive. The same ticks that transmit HGA (I. scapularis) are also responsible for Lyme disease and babesiosis. Each disease entity requires a full diagnostic workup, because amoxicillin treats Lyme disease but not HGA or babesiosis, and doxycycline alone does not treat babesiosis. Failure of fever to resolve beyond 6 or 7 days of treatment of a suspected tick-borne disease should heighten suspicion of an alternative disease organism.

BABESIOSIS

Perspective

Babesiosis is a tick-borne, malaria-like, acute febrile illness caused by intraerythrocytic protozoal parasites of the genus Babesia. Babesiosis has long been recognized as an important veterinary disease and probably was known in ancient times; in fact, it has been proposed that the fifth plague described in the Book of Exodus was actually babesiosis.

The first human cases of babesiosis were reported in Montana in 1904; investigators seeking the cause of RMSF examined blood smears from local inhabitants and described parasitic forms now known to be characteristic of Babesia. Since the late 1950s, several widely scattered cases (mostly in Europe) of human babesiosis have been reported in splenectomized persons. Babesia divergens, a species primarily infecting cattle, is the most common agent reported in Europe, but other species have been implicated as well, including Babesia bovis, Babesia equi, and a single case of Babesia caucasica infection. Two strains, WA-1, related to a canine pathogen B. gibsoni, and MO1, related to B. divergens, also have been found to cause disease in humans. In all of the reported cases, the course was fulminant and the disease usually fatal.

Since the late 1960s, more than 350 cases have been documented in the United States. Almost all of these cases were caused by Babesia microti, a rodent parasite, and occurred in the coastal regions of southern New England, where B. microti is endemic. New Jersey and the eastern part of Long Island recently have been found to be endemic with babesiosis as well. Babesiosis also has been reported in Maryland, Virginia, Georgia, Wisconsin, Minnesota, California, and Washington. These cases differ from the European cases in that most (approximately 80%) have occurred in persons with intact spleens. Up to now, significant morbidity has been low in the United States despite lack of specific therapy. However, the status of the disease in Long Island may cause more significant morbidity rates in U.S. endemic areas than was previously thought. Asplenic persons, the elderly, and otherwise immunosuppressed patients usually have more severe disease.

Principles of Disease

B. microti is associated with deer and mice, rather than cattle. The ecology of B. microti is similar to that of B. burgdorferi, the etiologic agent of Lyme disease, with the same major vector, I. scapularis, and the same mammalian reservoirs: white-footed mice, which host the larval and nymphal stages of the tick, and white-tailed deer, which host the adult ticks.

Human babesiosis results from accidental human intrusion on the natural cycle of infection. The nymphal form of I. scapularis tick most commonly transmits the disease to humans, although babesiosis also can be transmitted by the adult tick. I. scapularis nymphs measure only 1 to 2 mm long and thus are easily overlooked by the patient (see Fig. 132-4). In more than one half of all cases of babesiosis, patients cannot recall tick exposure. As is true for other tick-borne illnesses, the peak incidence of babesiosis is between May and August, coinciding with the nymphal feeding period and also the time of maximal human exposure in endemic areas. Babesiosis acquired through blood transfusion is well documented.

Clinical Features

Babesiosis has an incubation period of 1 to 4 weeks after tick exposure. A nonspecific flulike illness, with fever, chills, headache, fatigue, and anorexia, is characteristic. Less common manifestations are nausea, diaphoresis, depression, photophobia, myalgias, arthralgias, dark urine, emotional lability, and hyperesthesias. Unlike in Lyme disease, rash is not a feature of this illness; however, erythema figuratum, a widespread exanthema with well-established annular lesions, has been associated with septic babesiosis. Physical examination usually reveals normal findings, except for fever, which typically is present, and splenomegaly, which occurs in some patients. Meningeal signs are absent. More severe disease occurs in splenectomized patients; severe hemolytic anemia, hemoglobinuria, jaundice, renal insufficiency, ARDS, and disseminated intravascular coagulation can be seen in these cases. In a review of data for 139 patients from New York State, the mortality rate approached 6.5%. Some patients with babesiosis are only mildly ill, and asymptomatic infection also may occur, as demonstrated by serologic surveys in endemic areas. The diagnosis of babesiosis should be considered in any febrile patient from an endemic area during the tick season and should be part of the differential diagnosis for post-transfusion infections.

Diagnostic Strategies

The diagnosis may be established through microscopy, antibody detection through IFA staining, or PCR assay. Microscopic examination is done with thick and thin Giemsa-stained blood smears. Characteristic intraerythrocytic forms (pyriform, ring, tetrad) may be present. Babesiosis has been known to be misdiagnosed as malaria. The latter may be excluded by the absence of intracellular pigment granules, schizonts, and gametocytes. The presence of parasites in budding tetrad formation, resembling a Maltese cross, is more suggestive of babesiosis, although this finding is uncommon. Because parasitemia may vary, in suspected cases, serial smears over the course of several days may be necessary. An immunohistochemical assay has been developed that further allows for easier microscopic differentiation between babesiosis and malarial organisms.
The diagnosis can be confirmed by serologic studies. IFA antibody to *B. microti* is available through the CDC, and titers usually rise to 1:1024 or greater within the first few weeks of illness. IgM-indirect IFA is 91% sensitive and 99% specific in acute babesiosis. Serologic tests for Lyme disease, which shares a common tick vector with babesiosis, also should be performed; concurrent Lyme disease has been reported in up to 50% of cases of babesiosis. PCR testing also is now available and is thought to be highly sensitive and specific.

Parasitemia observed at 1 to 4 weeks after inoculation of blood from infected patients into gerbils or hamsters supports the diagnosis. Other nonspecific laboratory findings include mild to moderate hemolytic anemia, which is present in most patients, and resultant mild elevations in bilirubin and serum lactate dehydrogenase.

**Management**

Patients who have not undergone splenectomy generally recover without specific therapy, although prolonged malaise and fatigue are common. In patients with severe disease and in those who have had splenectomies, the combination of clindamycin (1.2 g twice daily IV or 600 mg three times a day PO) plus quinine (650 mg three times a day PO) has been shown to be effective and is currently the treatment of choice. An alternative regimen that may be better tolerated, especially by children and infants, consists of atovaquone (750 mg twice daily PO) plus azithromycin (600 mg once followed by 250 mg once a day PO), because up to 25% of patients may have an adverse effect from quinine. Pediatric doses need to be adjusted accordingly. Therapy should be continued for a minimum of 7 to 10 days. Other antimalarial drugs such as chloroquine and quinacrine are not effective. Fulminantly ill patients with marked degrees of parasitemia and hemolyisis have benefited from exchange transfusion. Effective live vaccines have been developed for bovine babesiosis but not yet for human disease.

**Colorado Tick Fever**

**Perspective**

Endemic to the Rocky Mountain area, Colorado tick fever is an acute tick-borne viral infection characterized by headache, back pain, biphasic febrile course, and leukopenia. The etiologic agent of Colorado tick fever is a small RNA virus of the genus *Orbivirus*, family Reoviridae. It is one of more than 500 viruses in the heterogeneous group of arthropod-borne viruses (arboviruses). Colorado tick fever has a sharply defined endemic zone encompassing mountainous and highland areas, from an altitude of approximately 4000 to more than 10,000 feet, in the Canadian provinces of British Columbia and Alberta and in at least 11 western states (California, Colorado, Idaho, Montana, Nevada, New Mexico, Oregon, South Dakota, Utah, Washington, and Wyoming). The largest number of cases has been reported in Colorado. The distribution of the virus coincides with that of its principal tick vector, *Dermacentor andersoni*, the Rocky Mountain wood tick. Although RMSF is transmitted by the same vector, that disease is far less common in Colorado. The cases of RMSF are outnumbered at least 20-fold by cases of Colorado tick fever.

**Principles of Disease**

The Colorado tick fever virus has been isolated from at least eight species of ticks, but *D. andersoni* is the only proven vector for humans. The tick is a significant reservoir for the virus because trans-stadial transmission (from larva to nymph to adult) of virus occurs, and the tick remains infected and infectious for life (up to 3 years). The primary vertebrate host species for Colorado tick fever virus maintenance are the chipmunk, *Tamias minimus*, and the golden-mantled ground squirrel, *Spermophilus lateralis*; many other vertebrate hosts have been identified as well, including a species of porcupine in Colorado in Rocky Mountain National Park. Larval and nymphal stages of *D. andersoni* ticks are responsible for transmission of Colorado tick fever virus among rodents, and overwintering of the virus is accomplished by nymphal and adult *D. andersoni*. Only adult ticks transmit Colorado tick fever virus to humans.

Several hundred cases per year are reported in the United States. The actual incidence undoubtedly is much higher, because many cases are diagnosed as nonspecific “viral illness,” and other cases may be very mild or entirely subclinical. Human susceptibility to Colorado tick fever is universal, but it occurs most commonly in young men, reflecting greater occupational and recreational tick exposure.

**Clinical Features**

After an incubation period of approximately 3 to 5 days (range, 0 to 14 days), a moderate to severe flulike illness occurs abruptly, with signs and symptoms similar to those in the early stage of RMSF. Fever, chills, headache, myalgia, lethargy, anorexia, and nausea are common; vomiting and abdominal pain occasionally are reported. Early physical findings are nonspecific. A macular or maculopapular rash has been reported in 5 to 12% of patients, but unlike the rash of RMSF, the rash of Colorado tick fever is not a prominent feature of the illness.

A distinct feature of the illness is a biphasic course that occurs in approximately 50% of patients, causing a characteristic “saddleback” fever curve. Initial symptoms resolve after 2 to 3 days, and the patient feels relatively well for 1 or 2 days, after which the fever, headache, and myalgias return. The second phase may be more intense than the first phase and generally lasts 2 to 4 days. There may even be a third febrile period. Alternatively, a single prolonged febrile illness may occur. Recovery from Colorado tick fever usually occurs within 2 weeks, but convalescence can be prolonged, especially in patients older than 30 years of age.

Colorado tick fever is a self-limited disease, and virtually all patients recover without sequelae. Reports of severe complications such as meningoencephalitis and hemorrhagic diathesis have been limited to children. Only a few fatal cases have been recorded.

**Diagnostic Strategies**

The peripheral leukocyte count often is depressed during the acute phase of illness to as low as 1000/µL, with a relative lymphocytosis. Transient thrombocytopenia can accompany the leukopenia and, less often, a mild anemia can occur. These hematologic abnormalities normalize during convalescence, but persistence of the virus in red blood cells causes a prolonged viremia even when clinical recovery is complete. Transfusion-acquired infection has been reported and is caused by this persistent viremia in asymptomatic blood donors. No one should donate blood for at least 6 months after recovery from Colorado tick fever.

The diagnosis of Colorado tick fever can be confirmed by serologic testing (IFA, neutralizing antibody, complement fixation, enzyme immunoassay) of acute and convalescent samples, but serologic study is of little help early on because of the slow rise of titers. The most rapid confirmation of Colorado tick...
fever, with corresponding elimination of concern about possible RMSF, is provided by direct immunofluorescent staining of virus in red blood cells in peripheral blood smears. PCR testing is now available for more rapid diagnosis.147

Management

Treatment for Colorado tick fever is supportive only. Most patients do not require hospitalization, but if RMSF remains a diagnostic possibility, initial treatment with tetracycline or chloramphenicol and a period of observation are necessary until the diagnosis of RMSF can be ruled out. Ribavirin has been suggested as a possible therapeutic agent but has not yet been tested.147

TICK PARALYSIS

Perspective

Tick paralysis occurs when an adult female tick attaches to a host and releases a neurotoxin that can produce cerebellar dysfunction or an ascending paralysis. Tick paralysis was recognized as early as the beginning of the 19th century. Howell, while traveling through Australia, wrote in 1824 of “the small insect called the tick, which buries itself in the flesh, and would in the end destroy either human or beast if not removed in time.”148

Tick paralysis has been reported worldwide, but most cases occur in the southeastern and northwestern regions of the United States, western Canada, and Australia. Cases have been reported to occur in clusters.149 Forty-three species of ticks have been found to cause tick paralysis in humans, other mammals, or birds. Most cases in North America and Canada are caused by Dermacentor andersoni (Rocky Mountain wood tick) and D. variabilis (American dog tick); species responsible for paralysis cases that also are associated with other tick-borne diseases include Amblyomma americanum (Lone Star tick), Ixodes scapularis (black-legged tick), and I. pacificus (western black-legged tick).149-151; in Australia, Ixodes holocyclus is primarily associated with this disorder. Family Argasidae ticks (soft ticks) also have been implicated. Tick paralysis usually occurs in the spring and summer months, and most reported cases are in children, primarily girls, probably because ticks are more easily concealed in longer hair. Among adults, however, more men than women acquire the disease.152

Principles of Disease

Tick paralysis is thought to be caused by a toxin secreted from the salivary glands of the tick during a blood meal.153 The toxin, ixobotoxin, affects sodium flux across axonal membranes without affecting the neuromuscular junction itself.153 The mechanism of action of the toxin is poorly understood, but it appears to produce a conduction block in the peripheral branches of motor fibers, resulting in a failure of release of acetylcholine at the neuromuscular junction. Electrophysiological studies have confirmed a rapid reversal of significant impairment of motor nerve terminal function after tick removal, indicating that the disturbance is not a result of a neuromuscular junction defect.154 Possible central sites of action of the toxin have been postulated to explain cases in which the clinical picture is dominated by cerebellar dysfunction.

Clinical Features

Onset of symptoms usually occurs from 4 to 7 days after the tick attaches. Initial manifestations include restlessness and irritability, followed by ascending flaccid paralysis, acute ataxia, or a combination of the two. Deep tendon reflexes are almost invariably lost. These signs and symptoms can progress rapidly over a few days to bulb involvement, respiratory paralysis, and ultimately death if the tick is not detected and removed.

The ascending nature of tick paralysis has been noted in most descriptions; however, ataxia and associated cerebellar abnormalities in the absence of muscle weakness may be seen. Thus, tick paralysis may sometimes manifest as “tick ataxia.” Isolated facial paralysis has been reported in patients with ticks embedded behind the ear. Fever, other systemic symptoms, and sensory deficits are unusual. Concomitant infection with Colorado tick fever has been reported.155

Diagnostic Strategies

No diagnostic tests to confirm tick paralysis are available other than the combination of the clinical scenario, the presence of a tick, and improvement after its removal. The Tensilon test yields a negative result in patients with this condition, and CSF is normal.154

Differential Considerations

Tick paralysis should be considered in the differential diagnosis for any patient thought to have Guillain-Barré syndrome, Eaton-Lambert syndrome, myasthenia gravis, poliomyelitis, botulism, diphtheritic polynuropathy, or any disease with an acute onset of ascending flaccid paralysis or acute ataxia.

Management

Treatment in the United States consists simply of removing the tick; improvement generally is seen within a few hours and complete recovery within 48 hours. Supportive care, including mechanical ventilation, may be necessary. The mortality rate is approximately 10%; nearly all patients who die are children. The recommended procedure for the removal of any tick (including ticks causing tick paralysis) is summarized in Box 132-2. Traditional methods such as burning, forceful removal, or application of petroleum, viscous lidocaine, or gasoline are not consistently successful and do not guarantee removal of mouthparts, where the salivary glands and toxin may remain. Retained mouthparts also may cause infection.

---

**Box 132-2** RECOMMENDED METHOD FOR TICK REMOVAL

1. Remove an embedded tick by grasping it with blunt forceps or tweezers as close to the point of attachment as possible.
2. Do not use bare fingers to remove ticks from animals or humans; when tweezers are unavailable, fingers should be shielded with a tissue, paper towel, or rubber glove.
3. Apply gentle, steady, upward traction with the forceps; do not twist or jerk the tick. Avoid squeezing or crushing the tick.
4. Do not handle the tick with bare hands. After removing the tick, thoroughly disinfect the bite site and wash hands with soap and water.
5. Dispose of ticks by placing them in a container of alcohol or flushing them down the toilet.

Tick paralysis in Australia often is more devastating than in the United States. Symptoms and signs of illness caused by the Australian tick, *I. holocyclus*, do not resolve and often worsen after tick removal. Hyperimmune serum is available in Australia and often is needed because symptoms may worsen up to 48 hours after removal.

**Prophylaxis with Insect Repellents**

Insect repellents have long been used to prevent mosquito bites. With recent increased public awareness of and concern about tick-borne illness, especially Lyme disease, skin and clothing repellents are now also being marketed for tick protection.

The most effective topical insect repellent known is *N*,*N*-diethyl-†m†-toluamide, commonly called DEET. A long-acting DEET formulation (U.S. Army Extended Duration Topical Insect and Arthropod Repellent [EDTIAR]), available in the United States as Ultrathon (3M), provides protection for 6 to 12 hours. Despite some earlier concerns, toxic and allergic reactions to DEET have been uncommon, and serious adverse effects are rare. Used as directed, concentrations up to 50% appear to be safe even in young children, although toxic encephalopathy can occur.156

Permethrin, actually a contact insecticide rather than a repellent, can be used as a clothing spray for protection against ticks. Applied to the clothing as an aerosol, it is nonstaining, nearly odorless, and resistant to degradation by light, heat, or immersion in water. Permethrin is toxic to the nervous system of insects, but in mammals it is poorly absorbed and rapidly inactivated. Reported adverse effects have been limited to the skin and are uncommon.

Both topical DEET and clothing impregnated with permethrin have been shown to be effective in field trials when used alone. Wearing protective clothing treated with permethrin, in addition to using DEET on exposed skin, provides the greatest degree of protection against tick bites.156

---

**KEY CONCEPTS**

- Tick-borne illnesses frequently are misdiagnosed as viral or bacterial infections. Early diagnosis can be facilitated by considering these diagnoses in patients who live in or recently have traveled to endemic areas and by routinely asking for a history of recent tick or insect bites in patients who present with febrile illnesses.
- Lyme disease should be suspected in patients who present with signs of a viral illness, monoarticular arthritis, meningitis, multiple neurologic abnormalities, or heart block. Diagnosis can be confirmed with serologic testing of acute and convalescent serum samples. Normal physiologic changes from bites should not be confused with erythema migrans. A significant amount of time of attachment is required for transmission of disease.
- Relapsing fever should be suspected in patients who present with recurrent viral-like illness associated with high fever. The diagnosis can be confirmed by identifying spirochetes on a blood smear obtained during a period of rising temperature.
- Ulceroglandular tularemia should be suspected in patients with slow-healing extremity ulcers associated with large lesions of regional adenopathy (buboes). The diagnosis can be confirmed with serologic testing.
- RMSF should be considered in patients who present with an unexplained febrile illness, even in the absence of a rash or known tick exposure. Delayed diagnosis and late initiation of specific antirickettsial therapy may lead to a fatal outcome. Treatment never should be delayed pending laboratory diagnosis.

CHAPTER 133

Tuberculosis

Peter E. Sokolove and Robert W. Derlet

PERSPECTIVE

History and Epidemiology

Tuberculosis (TB) has plagued humankind throughout recorded history. Clear evidence of tuberculous lesions of bone has been found in Egyptian mummified human remains that date to 3400 BCE.1 The presence of TB also has been microscopically confirmed in the mummies of small children, one from the dynastic period of Egyptian history and one from pre-Columbian southern Peru around 700 CE.1,3

Hippocrates (460 to 370 BCE) is credited for providing the first accurate clinical description of TB. He coined the term phthisis (“a melting or wasting away”) to describe the wasting character of the disease, which he noted also was associated with fever and incurable lung ulcerations.4 TB became a major public health problem during the Industrial Revolution. The corresponding urbanization of European cities led to overcrowding, widespread poverty, and poor hygienic conditions that were ideal for the epidemic spread of the disease throughout western Europe from the early 1600s through the 1800s.5 Approximately 25% of all adult deaths in Europe were caused by TB during this period, and in 1861 Oliver Wendell Holmes named it the “white plague.”4 TB gradually became a global epidemic as Europeans colonized North America and explored and colonized other parts of the world.5,6 The TB epidemic peaked in western Europe in the early 1800s and by 1900 had peaked in the Americas. Globally, the disease still has not reached a peak in some developing countries in Africa and Asia.7

Laënnec, who invented the stethoscope in 1816, accurately described the evolution of TB, from the small initial tubercle through all of its pathologic manifestations, in 1819.4 Twenty years later, Schönlein also recognized the tubercle as the fundamental anatomic lesion and named the disease tuberculosis.8 Koch identified the tubercle bacillus in 1882, and Roentgen’s discovery of x-rays in 1895 greatly improved the ability to diagnose TB early in the disease course.1,4

In 1892, Biggs instituted a comprehensive program of TB control in New York City that included public education, systemic surveillance, isolation of patients, nursing follow-up, improved sanitation, and free sputum testing.8,9 These types of programs and the subsequent introduction of the antituberculosis drugs led to an impressive decline in the incidence of TB throughout the 20th century. Between 1953 and 1985, TB cases decreased by an average of 5.8% per year.10 As recently as the 1970s, U.S. health officials believed that TB was well under control and could soon be eradicated.11 Unfortunately, as the incidence and perceived importance of the disease decreased, so did the public health programs to control it.12 The premature decline in government support for TB control programs made it impossible to manage the disease appropriately. The decline of the infrastructure dedicated to TB control during the late 1980s and early 1990s was compounded by new problems including the human immunodeficiency virus (HIV)–acquired immunodeficiency syndrome (AIDS) epidemic, increasing immigration from countries with high TB prevalence, increasing occurrence of TB in institutional living settings, escalating poverty, substance abuse, homelessness, and urban overcrowding. These factors contributed to a resurgence of TB in the United States from 1986 through 1992 and to the emergence of drug-resistant strains of Mycobacterium tuberculosis (MTB).12

Worldwide, the disease had become so widespread that in 1993 the World Health Organization declared TB a global emergency. TB is currently the world’s second leading infectious cause of death, and one third of the world’s population has been infected by TB.13 Each year more than 8 million people acquire active TB infection and nearly 2 million die from the disease.14

Elderly persons who harbor dormant infection that is reactivated constitute an important reservoir of MTB in the United States.15 Debilitating disease or immunosclerosis may predispose the affected person to reactivation. Nursing homes are particularly vulnerable to TB outbreaks because reactivation of disease in remotely infected persons may be followed by epidemic spread among the many susceptible hosts living in close quarters.

Immigration from endemic countries is another major factor.1,14 As reported in 2002, a majority of U.S. TB cases occur among foreign-born persons.16 The largest numbers of people with TB originate from Mexico, the Philippines, Vietnam, India, and China, accounting for more than one half of all TB cases among foreign-born persons.17 Homelessness also has contributed to the spread of TB in major urban centers. Homelessness often is associated with conditions that decrease resistance to TB, such as malnutrition, alcoholism, or substance abuse. MTB infection in the homeless population may quickly progress to active TB infection.19

The HIV/AIDS epidemic has had the greatest impact on the reemergence of TB in the United States.15 The pandemic of HIV-related TB has led to an increase in TB cases among non–HIV-infected people owing to the higher numbers of...
source cases in the community. The rate of TB among patients who are HIV-infected and TB skin test–positive is approximately 200 to 800 times higher than that estimated for the U.S. population overall.

The reemergence of TB has affected children. Between 1962 and the mid-1980s, the rates of childhood TB in the United States decreased an average of 6% a year. This trend has reversed along with the young urban adult trend, and the number of cases reported in children 4 years of age or younger increased 36% from 1985 through 1992. This increase reflected ongoing transmission of TB in the community, because TB in young children must result from recent infection.

After a 32-year decline, the number of TB cases in the United States increased 20% between 1986 and 1992. By 1992, roughly 14% more cases (26,673) were reported over the 1985 nadir. This trend, however, reversed in 1993, largely owing to the mobilization of new federal resources provided to the states for TB control and prevention. The number of reported cases during 1996 decreased in each age group, as well as in all ethnic groups. The number of reported cases in the United States during 2006 (13,767) represents a 48% decrease from 1992 and reflects the 14th consecutive year of decline.

Although the rapid resurgence of TB appears to be subsiding in the United States, there is no justification for complacency. Rates of newly diagnosed TB are still significant in different regions of the country and among certain demographic groups. The populations most likely to acquire and transmit TB infection commonly are seen by emergency physicians, who then necessarily play a key role in identification, prevention, and treatment.

Etiology

One microorganism, Mycobacterium tuberculosis, causes human TB in nearly all cases. Humans constitute the sole known reservoir for MTB. Two other pathogenic mycobacteria, Mycobacterium bovis and Mycobacterium africanum, have on rare occasions been implicated as causing TB. M. bovis is transmitted by drinking milk from diseased cows, but because pasteurization of milk is now common, it has become a relatively unusual cause of TB. M. africanum also is a rare cause of human TB. This mycobacterium is thought to be intermediate in pathogenicity between M. tuberculosis and M. bovis and has been documented to cause human TB, predominantly in Africa. Worldwide, MTB remains the major causative agent.

MTB is an intracellular, aerobic, nonmotile, non–spore-forming bacillus with a waxy lipid coat. This coating makes MTB resistant to decolorization with acid alcohol after staining—hence the term acid-fast bacillus (AFB). MTB grows slowly: Its generation time is 15 to 20 hours, compared with less than 1 hour for some common bacteria; cultures take 4 to 6 weeks to grow on standard solid media.

MTB produces neither endotoxins nor exotoxins. Its cell components are immunoreactive; some are immunosuppressive, and others are the agents of granuloma formation, macrophage activation, host toxicity, and modification of the immune response.

PRINCIPLES OF DISEASE

Transmission

TB is transmitted primarily by the respiratory route; transmission by other routes, such as direct inoculation, occurs primarily among health care workers. Patients with active disease expel MTB in liquid droplets during coughing, sneezing, and vocalizing. A single cough or 5 minutes of talking can produce 3000 infectious droplets, and sneezing can produce an even higher number. The droplets rapidly evaporate, and the desiccated bacilli circulate air-borne for prolonged periods. These infective particles, or droplet nuclei, measure 1 to 5 µm in diameter, contain one to three tubercle bacilli, and when inhaled can travel to the distal alveoli.

The susceptible host may become infected when only a few of the droplet nuclei are inhaled. Fomites are not important in the transmission of the disease, and patients’ rooms, eating utensils, and bed clothes do not require special decontamination procedures.

Pathogenesis

When infectious droplet nuclei are inhaled, the airflow through the bronchial tree tends to deposit them in the midlung zone on the respiratory surface of the alveoli. The deposition launches a complex series of immunologic events. Dannenberg has organized the complex pathogenesis of TB into four stages.

Stage 1

The first stage begins when an alveolar macrophage phagocytoses the recently inhaled bacillus. A macrophage from a resistant host can immediately destroy a less virulent bacillus. In these cases, no tuberculous infection develops and the process ends. If a virulent bacillus can overcome a macrophage’s microbicidal capability, the infection may progress to the next stage.

Stage 2

When the alveolar macrophage is unable to destroy the inhaled tubercle bacilli, the bacilli replicate until the macrophage...
Tubercle bacilli can survive dormant in this solid caseous multiply in this acidic, anoxic, extracellular environment.34 The infected macrophages also may be transported through lymphatics to regional lymph nodes, from which they can reach the bloodstream, with subsequent spread.

During this lymphohematogenous dissemination, the pathogens tend to distribute preferentially to lymph nodes, kidney, epithyses of long bones, vertebral bodies, meningeal areas, and the apical posterior areas of the lungs.25 These sites may be favored because of a high oxygen tension. Some investigators, however, believe that the lung apices are favored because of impaired clearance mechanisms from poor lymph flow.25

Stage 3

The third stage of TB begins 2 to 3 weeks after the initial infection, with development of the immune response that terminates the unimpeded growth of MTB.33 Cell-mediated immunity occurs through CD4+ helper T cells.35 When the T cell encounters mycobacterial antigens, it is activated and produces an expanded population of specific T cells. These T cells secrete cytokines (e.g., interferon-γ [IFN-γ], tumor necrosis factor) that attract and activate monocyte-macrophages. Once activated, the macrophages, containing previously ingested mycobacteria and their progeny, kill the bacilli. The destruction of the mycobacteria is associated with the formation of epithelioid cell granulomas and clearance of the organisms.34

Delayed-type hypersensitivity is mediated by cytotoxic CD8+ suppressor T cells.35 The cytotoxic cells kill nonactivated macrophages laden with mycobacteria and thus cause local tissue destruction as well. Delayed-type hypersensitivity results in the formation of caseating necrotic granulomas. This stops bacillary growth; mycobacteria, now extracellular, cannot multiply in this acidic, anoxic, extracellular environment.34 Tubercle bacilli can survive dormant in this solid caseous material for years.34 The host’s resistance determines whether the disease remains dormant or immediately progresses to active disease.

In the immunocompetent host with strong cell-mediated immunity, the primary lesion is effectively walled off by epithelioid cells. Eventually, the caseous center inspissates, and the disease is arrested, often for a lifetime.33 Similarly, at sites of lymphohematogenous spread, the mycobacteria are quickly destroyed, with little caseous necrosis, by a rapid immunologic response.35 The rapid destruction of the mycobacteria by cell-mediated immunity terminates the infectious process, and the only evidence of the infection is conversion to a positive tuberculin (purified protein derivative [PPD]) skin test result.35

This sequence of events from stage 1 to stage 3 represents the pathogenesis of primary TB in the immunocompetent patient.25 In most cases, primary TB is subclinical and self-limited. In the immunocompromised host, however, clinically active primary disease may develop rapidly after the initial MTB infection.

The less-resistant host with weak cell-mediated immunity relies more on delayed-type hypersensitivity to control the infection. The primary lesion is surrounded by nonactivated macrophages so it is not effectively walled off, and the caseous center expands, compromising more lung tissue. If the infection eventually can be contained by the host, any initial manifestations may go unnoticed, and the infection may be evident only radiographically as healed parenchymal calcifications of the primary or Ghon focus and of the regional lymph nodes.25 If host defenses are unable to contain the primary infection, however, as can occur in infants and immunosuppressed adults, the primary focus may become an area of advancing pneumonia.25 This process is called primary progressive TB. In addition, this host may be unable to control the infection at the sites of lymphohematogenous spread, resulting in formation of multiple uncontrolled caseous tubercles and development of disseminated TB.34 HIV-infected patients are particularly susceptible to primary progressive TB because HIV specifically targets CD4+ cells and macrophages.

Stage 4

The final stage usually occurs months to decades after an apparent recovery from the initial infection. TB may progress to stage 4 even in immunocompetent persons. Usually, host factors lead to decreased resistance and reactivation of dormant foci of MTB. The progression is due to liquefaction and cavity formation.

The liquefied tubercle serves as an excellent growth medium for the mycobacteria. The large numbers of extracellular bacilli stimulate delayed-type hypersensitivity, which secondarily causes local damage. The tubercle eventually erodes through the bronchial wall and drains its contents, forming a cavity. The liquefied caseous material, teeming with mycobacteria, enters other parts of the lung and the outside environment. The spilling of this liquefied material within the lung may produce a caseous bronchopneumonia.34

The cavity formed at the site of the initial focus remains a significant lesion. Cavities provide optimal conditions for mycobacterial growth. The oxygen tension is increased, and the host’s defenses are ineffective at interrupting multiplication of the mycobacteria within a cavity.34

### CLINICAL FEATURES

The initial infection with MTB most often is asymptomatic in otherwise healthy persons. Mild fever and malaise may develop in association with the immune response at 4 to 6 weeks, but generally the primary infection is clinically insignificant.36 Conversion to a positive PPD skin test result may be the only means of diagnosing the infection. Clinically active TB develops in 8 to 10% of otherwise healthy PPD converters who do not take prophylactic agents—3 to 5% in the first 2 years (acute primary TB) and another 5% during the remainder of life (reactivation TB).39 By contrast, in persons also infected with HIV, progression to acute primary TB occurs at a rate of 37% within 6 months and then to active TB at a rate of 7 to 10% per year.39

Reactivation of dormant foci is responsible for the major clinical manifestations of TB.39 Exogenous reinfection of patients with well-documented previous TB infection causes clinical disease indistinguishable from reactivation TB.37 Because it may be incorrect to label all late-onset cases as reactivation disease, postprimary TB is the preferred term. Postprimary TB is active or chronic disease in a patient previously infected. In the United States and other developed countries, reactivation is thought to be the primary mechanism of postprimary TB. Exogenous reinfection has played a role in circumstances in which contagion levels are high, as in outbreaks of TB, in developing countries, or in immunocompromised hosts.33,39
**Patient’s History**

**History of Present Illness**

Clinically significant pulmonary TB often is indolent, and signs and symptoms are absent or minimal until the disease advances. The patient also may experience a systemic reaction to the infection. The systemic reaction, thought to be mediated by cytokines, especially tumor necrosis factor α, causes the constitutional symptoms of anorexia, weight loss, fatigue, irritability, malaise, weakness, headache, chills, and, most commonly, fever. The fever usually develops in the afternoon; defervescence occurs during sleep, leading to the classic night sweats of TB.

Cough is the most common symptom of pulmonary TB. Initially it may be nonproductive, but as caseation necrosis and liquefaction develop, mucopurulent and nonspecific sputum typically is produced. Hemoptysis, caused by caseous sloughing or endobronchial erosion, usually is minor but often indicates extensive lung involvement. Many asymptomatic patients present for medical attention because they are alarmed by the hemoptysis.

Patients also may complain of pleuritic chest pain, which is caused by parenchymal inflammation adjacent to the pleural surface. Dyspnea with chest pain may indicate a spontaneous pneumothorax. Shortness of breath from parenchymal lung involvement is unusual, however, and if present indicates extensive parenchymal disease or tracheobronchial obstruction. Table 133-1 shows the frequency of symptoms found in one study of patients with culture-proven pulmonary TB. The clinical manifestation of TB in patients presenting to the emergency department (ED) may be especially confusing. In one study, only one third of ED patients with active pulmonary TB had pulmonary chief complaints, only 64% ever reported a cough, and only 8% had hemoptysis.

Any vague systemic disorder or fever of unknown etiology may represent TB. Atypical presentations are particularly common in infants, the elderly, and immunocompromised persons. In infants and young children, the development of large hilar lymph nodes is common; such nodes may compress a bronchus, leading to atelectasis and possibly obstructive pneumonia; the child may have a “brassy cough.” A node also may erode through the bronchial wall, causing symptomatic endobronchial disease and allowing endobronchial spread of tuberculous pneumonia to other areas of the lungs. By contrast, fewer elderly persons present with respiratory symptoms. The diagnosis may be masked by coexistent disease and non-specific presenting symptoms.

Pulmonary TB should be considered in elderly patients with chronic cough and failure to thrive.

Clinical manifestations of TB in patients co-infected with HIV are even more subtle and nonspecific, especially because these patients are vulnerable to opportunistic infections and neoplasms that can cause the same constitutional symptoms as in TB. A synergy between the two infections (MTB and HIV) leads to a greatly increased viral load. Active TB with HIV co-infection has been associated with an increased risk for opportunistic infections and death. Patients with advanced HIV infection also commonly have extrapulmonary involvement (seen in 30%), as well as combined pulmonary and extra-pulmonary TB (in 32%).

**Risk Factors**

All patients in the ED who have been coughing should be screened for the presence of TB risk factors (Box 133-1). Risks for acquiring TB may also be stratified by age. Because infants and toddlers have poorly developed cell-mediated immunity, they have a much higher incidence of TB than adults. Children 5 to 10 years of age are relatively resistant to TB. Infants and toddlers commonly have extrapulmonary disease and acute lower and midlung bronchopneumonia that rarely progresses to cavitary disease. Young adults show the adult pattern of apical pulmonary disease, including cavity formation, suggesting reactivation. Because of decreased immunocompetence, elderly persons typically have disease manifestations similar to those in young children. Patients with a history of PPD conversion should be asked about the presence of medical conditions associated with increased risk for the development of active postprimary disease through reactivation (Box 133-2).

Patients with a history of active TB should be asked about all antituberculosis medications previously or currently being taken and about compliance. Failure to improve after 2 months on an appropriate regimen may signal nonadherence to therapy or the presence of a resistant strain.

### Box 133-1

**POPULATION GROUPS WITH INCREASED RISK FOR TUBERCULOSIS**

- Close contacts of known case
- Persons with HIV infection
- Foreign-born from Asia, Africa, Latin America
- Medically underserved, low-income populations
- Elderly persons
- Residents of long-term care facilities (e.g., nursing homes, correctional facilities)
- Injection drug users
- Groups identified locally (e.g., homeless, migrant farmworkers)
- Persons who have occupational exposure

HIV, human immunodeficiency virus.

Endobronchial Spread

Endobronchial spread is the most common complication of cavitary disease. It is manifested radiographically as 5- to 10-mm, poorly defined nodules clustered in dependent portions of the lungs. These nodules may rapidly coalesce into parenchymal consolidation—so-called galloping consumption. When a cavity drains its highly infectious material into the bronchial tree, the airways not only spread the infection but also develop endobronchial TB. Bronchiectasis commonly complicates endobronchial TB. Bronchial stenosis may result from extensive damage caused by endobronchial TB or from direct extension of infection from tuberculous adenitis or from lymphatic dissemination to the airway. Tuberculous bronchostenosis may appear radiographically as persistent segmental or lobar collapse, lobar hyperinflation, and obstructive pneumonia.

Tracheal TB and laryngeal TB are less common than endobronchial TB. Laryngeal disease is the most infectious form of TB; it results from the proximal extension of lower airway disease, pooling of infected secretions in the posterior larynx, or hematogenous dissemination to the anterior larynx. Patients with laryngeal TB also usually have active pulmonary disease.

Superinfection

Extensive TB infection often heals with open cavities and areas of bronchiectasis. Superinfection may occur with a wide variety of organisms, including Aspergillus fumigatus. The characteristic finding on chest radiographs is the aspergilloma or “fungus ball” (Fig. 133-2). Aspergillomas are of particular clinical significance because they may cause massive and fatal hemoptysis.

Hemoptysis

Mild hemoptysis is a common complication of acute infection. TB also causes massive hemoptysis. The destruction of lung parenchyma leads to rupture of blood vessels. A tuberculous lesion or cavity may erode into a pulmonary artery, leading to
pseudoaneurysm formation (Rasmussen’s aneurysm) with potentially fatal hemoptysis. This complication has become uncommon since the development of antituberculosis medications. Alternatively, superinfection of cavities by invasive organisms or tumor development in scarred lung may cause erosion of bronchial or pulmonary vessels, with resultant major hemorrhage. Affected patients often require emergency surgical resection or selective embolization.

Primary Tuberculous Pericarditis

Primary tuberculous pericarditis usually results from direct extension of infection from the tracheobronchial tree, mediastinal or hilar lymph nodes, sternum, or spine. Pericardial involvement also may result from hematogenous spread secondary to acute miliary TB or from another focus elsewhere in the body. In the United States, TB is the leading cause of pericarditis among HIV-infected patients, with a prevalence of up to 15%. The predominant symptoms are cough, chest pain, and dyspnea, and the most common signs are cardiomegaly, an audible rub, fever, and tachycardia. Complications of pericardial TB include pericardial effusion, constrictive pericarditis, myocarditis, and cardiac tamponade. Cardiac tamponade may result from accumulation of pericardial fluid but also may occur if enlarging lymph nodes rupture into the pericardium. Emergency echocardiography reliably confirms the presence of pericardial fluid.

Diagnostic Imaging

Plain radiography of the chest is the most useful study for making a presumptive diagnosis of pulmonary TB. Chest radiographic abnormalities are not limited to the classic upper lobe cavitory infiltrates. Primary TB infection and postprimary disease each have distinctive radiographic features. A normal appearance on the chest radiograph has a high negative predictive value and is therefore useful in screening ED patients for active pulmonary TB. However, the false-negative rate is approximately 1% among immunocompetent adults and increases to 7 to 15% among HIV-positive patients. Therefore, depending on the clinical circumstances, absence of specific abnormalities on the chest radiograph does not always exclude active TB, especially in patients with concomitant endobronchial disease and HIV infection.

Primary Tuberculosis

Chest radiographic manifestations of primary disease in adults often are not recognized as TB. Primary tuberculous infiltrates can occur in any lobe. With any age group, a pneumonia infiltrate with enlarged hilar or mediastinal nodes should strongly suggest the diagnosis. The infiltrate usually is homogeneously and most commonly involves a single lobe. Thus, primary TB may appear radiographically identical to a bacterial pneumonia, with associated lymphadenopathy, if present, being the only distinguishing feature.

Lymphadenopathy is considered the radiologic hallmark of primary TB in children but is seen less commonly in adults. When present, adenopathy usually is unilateral and associated with parenchymal infiltrate (Fig. 133-3). It may occur bilaterally or, more rarely, may be an isolated finding on chest radiography. Massive hilar adenopathy is more common in young children. As a result, atelectasis, resulting from airway compression by adjacent enlarged nodes, is a likely finding in children younger than 2 years but is less common among older children and adults.
Other primary TB chest radiographic findings include a moderate to large pleural effusion, which often is an isolated finding whose prevalence increases with age; miliary TB (characterized by the presence of innumerable, 1- to 3-mm noncalcified nodules dispersed throughout both lungs with mild basilar predominance), which is mainly a threat to children younger than 2 years, immunocompromised patients, and the elderly; and tuberculomas, well-circumscribed nodular lesions of the parenchyma thought to be a result of healed primary TB. When the healed primary focus is visible on the chest radiograph as a calcified scar, it is known as the Ghon focus. Calcified secondary foci of infection are known as Simon's foci. A Ghon focus associated with calcified hilar nodes is called a Ranke complex. A right-sided predominance in the distribution of Ghon’s foci and Ranke’s complexes is well recognized and probably reflects the higher statistical probability that an air-borne infection will affect the right lung. Calcification seen on the chest radiograph indicates healing, but viable bacilli may still exist in a partially calcified lesion.

When resolution does not occur, the result is progressive primary TB, which appears radiographically as progressive parenchymal consolidation often including secondary foci in the upper lobes. In some patients, the primary tuberculous pneumonia breaks down into multiple cavitary lesions or a single large abscess. These chest radiographic findings may easily be confused with the findings in postprimary TB.

Postprimary Tuberculosis

Postprimary TB typically appears as an upper lung infiltrate or consolidation, with or without cavitation. The lesion may be small or extensive and usually is located in the apical or posterior segment of the upper lobe but may appear in the superior segment of the lower lobe. Postprimary disease also occurs in the lower lung. In addition, bronchogenic spread can occur, leading to involvement of multiple lobes (Fig. 133-4). The patient with bilateral upper lobe disease is extremely likely to have TB. The other important, recognizable characteristics of postprimary disease are fibrosis and cavitiation.

The initial lesion of postprimary TB is a poorly defined, heterogeneous alveolar opacity called an exudative lesion. These lesions are not purely exudative in that they are associated with a fibrotic pattern of nodules and a few fine, linear densities. Unchecked, the infection may rapidly progress to lobar or complete lung opacification and destruction. Postprimary TB, however, usually runs a chronic course characterized by reactive fibrosis, and in most cases the initial exudative lesions gradually are replaced by more well-defined reticular and nodular opacities or “fibroproductive” lesions.

Fibroproductive lesions often are irregular and angular in contour, have strands extending toward the hilum, and demonstrate calcification of one or more nodules. This pattern is characteristic of granulomatous disease and rarely is found in other bacterial infections. As fibrosis continues, distortion of normal vascular and mediastinal structures secondary to contraction and shrinkage of the scar may be apparent. Severe fibrosis with upper lobe volume loss may eventually lead to retraction of the interlobar fissure and upward displacement of the hilum. The chest radiographic appearance at this stage has been variably referred to as “old scarring,” “no active disease,” or “fibrotic, apparently well-healed TB.” Many of the patients have positive sputum culture results, and infectivity cannot be accurately assessed by chest radiography. Only serial radiographs can reliably differentiate active from inactive disease. Lack of radiographic changes over a 4- to 6-month interval generally indicates “inactive” or, more precisely, “radiographically stable” disease.

Cavitation should alert ED personnel to the high infectivity of the patient and the potential for associated complications such as bronchogenic spread of TB when an area of caseous necrosis liquefies, with consequent communication with the bronchial tree (see Fig. 133-4). Cavities usually are multiple and range in diameter from a few millimeters to several centimeters. The walls of the cavities initially are thick and rough and become thinner and smoother with healing (Fig. 133-5). A hazy, parenchymal reaction around a cavity with an ill-defined wall strongly suggests an active lesion. Most cavities heal by obliteration, often leaving a small linear or stellate scar; others remain patent and become thin-walled bullae.
Although pulmonary TB usually induces chest radiographic changes, patients with sputum cultures positive for MTB may nevertheless demonstrate normal radiographic findings. In a series of 103 patients, 10 people (9.7%) with confirmed pulmonary TB had normal findings on their chest radiographs.\(^{56}\) Chest radiographs also may be normal in appearance in patients with endobronchial TB.\(^{41,60}\)

Chest radiographs of patients with pulmonary TB and HIV infection may be atypical in approximately one third of cases.\(^{61}\) However, the radiographic appearance of disease is heavily influenced by the degree of immunocompromise. Patients with late HIV infection more often demonstrate mediastinal adenopathy or atypical infiltrates and less often have cavitation.\(^{52,63}\) Severe immunosuppression has been reported to be associated with a miliary pattern of disease on chest radiographs.\(^{24}\) Conversely, chest radiographs of patients with early HIV infection are more similar to those of patients without HIV infection, with upper lobe infiltrates, more cavitation, and less adenopathy.\(^{64}\) A normal chest radiographic appearance also is common in patients with HIV infection. In one study, chest radiographic findings were normal in 14% of HIV-infected patients, including 21% of those with CD4+ counts below 200/µL and 5% of those with CD4+ counts greater than 200/µL.\(^{61}\)

**Microbiology**

**Sputum Studies**

If the clinical or chest radiographic findings suggest the diagnosis of pulmonary TB, mycobacteriologic studies of the patient's sputum should be ordered. Spontaneously produced sputum collected under direct supervision is preferred, and early-morning samples are the best diagnostic specimens.\(^{25}\) Classically, three initial sputum specimens should be obtained on different days. A positive smear supports a presumptive diagnosis, and the number of bacilli seen correlates with infectivity. For patients who are not producing sputum, nebulized induction of sputum and gastric aspiration of swallowed respiratory secretions are the methods of choice for collecting samples.\(^{65}\) The diagnostic yield is higher for nebulizer-induced sputum samples than for gastric aspirates in adult patients with TB, but in some patients, especially children, gastric aspirates may be the only obtainable specimens. Induction of sputum with nebulization may increase the risk of TB transmission to health care workers and should be performed only in specially ventilated rooms, preferably not in the ED.

When sputum is not diagnostic in adults, fiberoptic bronchoscopy with bronchial washings, brushings, and bronchoalveolar lavage or transbronchial biopsy may be necessary for laboratory diagnosis of TB.\(^{65}\) In children, sputum obtained by bronchoscopy has a lower culture yield, so this technique is used less often to obtain sputum from pediatric patients.\(^{66}\)

**Direct Microscopy**

Direct microscopic examination of a stained sputum specimen for AFB (i.e., an AFB smear) is the most rapid laboratory test widely available to support a presumptive diagnosis of TB (Fig. 133-6), and results usually are available within 24 hours.\(^{67}\) Although nontuberculous mycobacteria can cause pulmonary disease, they are less common than MTB and vary by geographic location and population of patients. Fluorochrome stains are more sensitive than the traditional Ziehl-Neelsen or Kinyoun methods for the detection of AFB from clinical specimens.\(^{66,67}\) Negative findings on an AFB smear, however, do not rule out active pulmonary TB, because microscopy is relatively insensitive when performed on samples with small numbers of bacilli. At least 5000 bacilli/mL of sputum must be present for a positive result by microscopy.\(^{67}\) Because cavitary disease is associated with great numbers of bacilli, the diagnostic yield of microscopy increases with cavitation. Concentrated smears are prepared by decontamination, liquefaction, and centrifugation of sputum, and such smears may be more sensitive than unconcentrated samples.\(^{14}\) Overall, AFB smears have a sensitivity of 20 to 80% and a specificity of 90 to 100%.\(^{67}\) Despite its limitations, microscopy remains an essential diagnostic test because of its ease of performance, low cost, rapid turnaround time, and reasonable diagnostic yield.

**Culture**

A presumptive diagnosis of TB based on a positive sputum smear usually is confirmed by isolating MTB by culture. Traditional culture methods using solid media require 3 to 8 weeks for colony formation. The development of liquid culture systems has shortened the detection time to 7 to 14 days. A number of liquid culture systems are available for detection of MTB. For example, the BACTEC (Becton Dickinson, Franklin Lakes, NJ) method measures 14CO2 produced by growing mycobacteria when they metabolize the 14C-labeled palmitic acid contained in the system, and the mycobacteria growth indicator tube (MGIT) method measures mycobacterial oxygen consumption with a fluorescence assay.\(^{67}\)

Sputum culture is more sensitive than microscopy for detecting MTB and is still considered the “gold standard” diagnostic modality. Liquid culture can detect 10 to 100 bacilli/mL, compared with 5000 to 10,000 bacilli/mL for AFB smear. When the presence of mycobacteria is established, the specific identification of MTB may be accomplished by subjecting the initial mycobacteria to various isolation techniques. These include the detection of pigmentation on solid culture media, various biochemical tests, high-performance liquid chromatography, and nucleic acid probes.\(^{67}\)

**Drug Susceptibility Testing**

Because of the emergence of multidrug-resistant MTB, all initial isolates of MTB should be tested for susceptibility to isoniazid (INH), rifampin (RIF), and ethambutol (ETH).\(^{66}\) Further susceptibility testing should be performed when resistance to one of the three agents is detected or if the patient has had previous TB treatment, has been exposed to a drug-
resistant contact or source, or has demonstrated a positive result on sputum cultures beyond 3 months of therapy.69 Conventional susceptibility testing detects selective growth of drug-resistant TB on media containing antituberculosis drugs. For first-line agents, this requires waiting until 4 to 7 days after a positive culture result is obtained; testing for susceptibility to other drugs may require 2 to 3 months. The BACTEC and MGIT systems also can be used for rapid drug susceptibility testing, with results obtained in fewer than 12 days.67 Other new approaches to susceptibility testing include flow cytometry, genotypic sequence–based methods, and bacteriophage viability testing.67,69

Nucleic Acid Amplification Tests
A number of nucleic acid amplification assays are available to assist in the rapid diagnosis of MTB infection, including polymerase chain reaction (PCR) tests, the Mycobacterium tuberculosis direct test (MTD'T), and the ligase chain reaction.67 These tests can be used directly on clinical specimens but at present are of limited utility in the diagnosis of MTB. They are undergoing refinement, however, and may become valuable tools in the future. Problems include high cost and potential for suboptimal performance in clinical settings because of factors such as variability in laboratory methodology, potential for specimen contamination, and lower-than-expected sensitivity.14,66 Sputum smears are still needed to evaluate for infectiousness, because these tests are unable to differentiate active from treated infection. Sputum cultures also are still needed, because these tests do not assess drug susceptibility.14 Nucleic acid amplification tests may be useful, however, when findings on standard clinical and microbiologic tests are negative or inconclusive. The PCR assay may provide a method for confirming the diagnosis of TB within a few hours. PCR testing is based on a DNA amplification technique that bypasses the delays inherent with mycobacterial cultures. It allows the in vitro synthesis of millions of copies of a specific MTB DNA segment.70 Diagnostic techniques based on PCR allow direct testing of routine clinical specimens to confirm the diagnosis of TB in hours. Test performance varies greatly, depending on whether the sputum sample is AFB smear–positive or –negative. For example, for AFB smear–positive specimens, the Roche (Roche, Nutley, NJ) Amplicor system has a sensitivity of 95 to 96% and specificity of 100%. When it is applied to AFB smear–negative specimens, the sensitivity drops to 48 to 53%, with a specificity of 96 to 99%.67,71 The MTD'T enzymatically amplifies a 16S ribosomal RNA (rRNA) segment that is specific for MTB complex species. Preliminary studies suggest that the MTD'T has excellent sensitivity (86 to 98%) and specificity (97 to 100%) for the rapid identification of MTB and can be performed in approximately 5 hours. As with PCR assays, specimen quality and the degree of AFB smear positivity affect test performance.67,72

The Ligase Chain Reaction
The ligase chain reaction amplification assay involves repetitive cycles of high-temperature DNA denaturation, oligonucleotide annealing, and ligation. The Abbott Laboratories (Abbott Park, IL) LCx assay has a sensitivity of 98% for AFB smear–positive specimens and 27% for AFB smear–negative specimens and a specificity of 100% (equal to that of culture).67 When LCx was compared with PCR assay and MTD'T in a clinical trial, no significant difference in sensitivity or specificity was found among these three tests.73 Tuberculostearic acid (TSA) is a fatty acid found only in mycobacteria. It can be detected with gas chromatography–mass spectrometry in clinical specimens containing small numbers of bacilli. TSA testing is not frequently used, because the equipment and expertise needed to run this test are not widely available outside specialized research laboratories.74

Interferon-γ Levels
IFN-γ is a cytokine associated with cell-mediated immunity. Determination of IFN-γ levels also can be used as a diagnostic test for tuberculous pleural effusions, ascites, and pericardial effusions. Clinical studies have reported sensitivity and specificity of 100% and 100%, respectively, for assay of IFN-γ in pericardial fluid and 78% and 97% in pleural fluid.75,76 IFN-γ assay can be used independently, as a confirmatory test, or in combination with other tests, such as PCR assay.76

Serology
Serodiagnosis of TB, if such testing were readily available, would be a minimally invasive approach to rapid diagnosis. Using an enzyme-linked immunosorbent assay (ELISA) to diagnose TB from serum would be especially useful in patients who cannot produce sputum. Although ELISAs have been developed for several MTB antigens, in practice, no serodiagnostic approach to the diagnosis of TB currently is in widespread clinical use in the United States. Limitations of the ELISA include inadequate accuracy and reproducibility, inability to distinguish active from latent infection, poor discrimination between MTB and other mycobacteria, and relative cost.66,67

Tuberculin Skin Test
While newer diagnostic tests undergo development, the tuberculin skin test remains the best tool available for detecting latent MTB infection. The tuberculin test is based on the principle that MTB infection induces sensitivity to certain antigens of the bacillus. These antigens are contained in the tuberculin preparation called PPD. In a person infected with TB, the PPD test result usually turns positive 3 to 8 weeks after the infection, when the immune response is developed.67

The standard 0.1-mL dose used in skin testing contains 5 tuberculin units (TU). This dose is administered intradermally with the needle bevel up, using the Mantoux technique. A properly placed needle should leave a blanched, distinct wheal 6 to 10 mm in diameter.68 If the tuberculin dose is incorrectly administered, the test may be repeated immediately at a site several centimeters away. Various types of test kits and applicators are available (Heaf and tine tests), but for diagnostic purposes the Mantoux test with PPD (5 TU) is preferred.29,68,77

Tests are “read” 48 to 72 hours after administration of PPD. The largest diameter of palpable induration is measured and recorded in millimeters; erythema by itself is not measured. The precise measurement that denotes a positive test result depends on the patient’s other clinical factors. The current CDC guidelines use 15 mm of induration as a positive test for people without TB risk factors78 (Table 133-2).

Some persons with previous TB infection gradually lose their hypersensitivity reaction to PPD and may react weakly or not at all. The PPD test, however, can restimulate or enhance their hypersensitivity, so that a subsequent test does elicit a positive reaction. This phenomenon is called the booster effect. This boosted reaction may be mistaken for a new infection. To eliminate the booster effect as a confounding factor, a two-step testing method is recommended for

‡These persons should not be screened in the absence of an indication.

†Medical conditions that increase the risk of development of tuberculosis in the presence of latent tuberculosis infection include silicosis, end-stage renal disease, malnutrition, diabetes mellitus, carcinoma of the head and neck or lung, immunosuppressive therapy, lymphoma, leukemia, loss of more than 10% of ideal body weight, gastrectomy, and jejunooileal bypass.

‡These persons should not be screened in the absence of an indication.

HIV, human immunodeficiency virus.

People who undergo serial PPD screening (health care workers). If the result of the first test is negative and the person does not have a documented negative PPD test result during the previous 12 months, a second test is done 1 week later using the same dose. If the second test is positive, it is most likely to represent a boosted reaction and the person should be considered previously infected. If the second test result remains negative, the person is considered uninfected and a positive reaction to a subsequent test indicates new infection.

Infection with nontuberculous mycobacteria may cause a false-positive PPD result. These reactions tend to be smaller than the true-positive reaction to MTB infection. Similarly, bacille Calmette-Guérin (BCG) vaccination may produce a PPD reaction that generally is mild and deteriorates with time. A large reaction to PPD and a long time interval between BCG vaccination and the current skin test make it more likely that the reaction is due to MTB infection. Because the BCG vaccine is imperfect in protecting against MTB infection and because most vaccinated persons come from areas of high TB prevalence, the CDC recommends that tuberculin skin test results be interpreted without regard to BCG vaccination status.

Many conditions can lead to false-negative reactions to PPD testing (Box 133-3). The incidence of false-negative results in one study was 25% among the 200 patients with active TB. Therefore, the clinical significance of a negative PPD result is best determined by considering other clinical factors. Despite some limitations, PPD skin testing remains useful to diagnose individual patients, to screen populations, and to evaluate infected persons for prophylactic treatment (Table 133-3).

Differential Considerations

Pulmonary Tuberculosis

Bacterial Pneumonia

Segmental or lobar infiltrates on chest radiographs in bacterial pneumonia may easily be confused with those seen in TB, especially primary disease. Compared with TB, however, bacterial pneumonias usually arise with more profound symptoms of systemic toxicity, a more acute onset, and an elevated white blood cell count. In pulmonary TB, there is no prompt response to antibiotics, as seen in bacterial pneumonia.

*We define close contact as at least 12 hours of contact with a person with infectious tuberculosis, but well-established criteria for such contact are lacking.
†Persons with recent infection include children younger than 4 years and persons found to have tuberculin conversion, defined as an increase in induration of at least 10 mm on a tuberculin skin test within a 2-year period. HIV, human immunodeficiency virus.

Fungal and Nontuberculous Mycobacterial Infections

Histoplasmosis, coccidiodomycosis, and blastomycosis, as well as nontuberculous mycobacterial infections (mainly with Mycobacterium avium complex and Mycobacterium kansasi), may be radiologically indistinguishable from TB. The incidence of these infections is influenced by geographic location. Nontuberculous mycobacterial infection most commonly involves chronic pulmonary infection in HIV-infected patients. Immunocompetent persons also may become infected with MTB, especially patients with chronic lung disease such as cystic fibrosis. Other important risk factors include work in the mining industry, warm climate, advancing age, and male gender.

Pneumonias in Patients with Human Immunodeficiency Virus

Bacterial pneumonias including upper lobe Pneumocystis pneumonia (due to Pneumocystis jiroveci) and, rarely, Nocardia and Rhodococcus infections may mimic TB in patients with HIV infection.

Cavitary Lesions

Lung abscess or cavitating pneumonia caused by Klebsiella pneumoniae, Staphylococcus pyogenes, or aspiration may appear similar to cavitary TB on chest radiographs. In older patients, especially smokers, bronchogenic carcinoma may mimic TB; this is particularly true of squamous cell carcinoma, which tends to cavitate. Because cancer may cause a focus of TB to spread, the two diseases may be present simultaneously. Other causes of nontuberculous cavitary lesions include M. avium complex infection in HIV-negative patients, pulmonary infection secondary to pulmonary embolus, Wegener’s granulomatosis, and upper lobe bullous disease secondary to emphysema or neurofibromatosis.

Upper Lobe Infiltrate with and without Fibrosis

A radiographic pattern characterized by presence of an upper lobe infiltrate with or without fibrosis may be seen with atypical mycobacteria, anklyosing spondylitis, silicosis, collagen vascular diseases, lymphomas, and actinomycosis. Upper zone fibrosis and volume loss can occur in the later stages of extrinsic alveolitis, allergic bronchopulmonary aspergillosis, and sarcoidosis. The presence of calcification suggests TB.

Mediastinal Lymphadenopathy

The main considerations in the differential diagnosis for adenopathy include lymphoma and sarcoidosis. In sarcoidosis, lymphadenopathy usually is bilateral, symmetrical, and asymptomatic. Lymphadenopathy in TB tends to be unilateral or, if bilateral, is asymmetrical and associated with parenchymal lung disease. Lymphoma tends to involve very bulky mediastinal lymphadenopathy.

Extrapulmonary Tuberculosis

Tuberculous infection involving multiple sites most commonly is seen in patient populations less capable of containing MTB infection such as infants, the elderly, and immunocompromised persons. Extrapulmonary TB accounted for roughly 15% of newly diagnosed TB cases in the United States before the HIV epidemic. As reported in 2002, approximately 21% of TB patients in the United States had extrapulmonary disease, and another 7.5% had both pulmonary and extrapulmonary infection. In children younger than 4 years, approximately 25% of TB infections are extrapulmonary. Among HIV-infected persons, extrapulmonary TB infection becomes progressively more common as CD4+ counts fall below 350 cells/µL. One study of patients with TB concurrent with advanced HIV infection reported that 38% had only pulmonary disease, 30% had extrapulmonary TB alone, and 32% had both pulmonary and extrapulmonary TB.

Extrapulmonary TB may occur in multiple sites, with relative frequencies of 42% for lymphatic, 18% for pleural, 12% for bone or joint, 6% for genitourinary, 6% for meningeal, 5% for peritoneal, and 11% for other sites. The lymph nodes are the most common site of extrapulmonary TB for both otherwise normal and HIV-infected patients. Involvement of the meninges is more common in young children than in other age groups (present in approximately 4% of children with TB), and the incidence of TB in the remainder of the extrapulmonary sites increases with age. Less commonly involved locations for extrapulmonary TB include the skin, heart, pericardium, thyroid gland, mastoid cells, sclerae, and adrenal glands.

Lymphadenitis

Tuberculous lymphadenitis (scrofula) is the most common form of extrapulmonary TB. Scrofula is common in children but most commonly is seen in young adult women, usually of minority races. The patient usually has an enlarging, painless, red, firm mass in the region of one or more lymph nodes, most commonly in the anterior or posterior cervical chain or the supraclavicular fossa. Early on, the nodes are discrete, rubbery masses that are freely mobile, and the overlying skin is normal. Eventually, the nodes may become matted and...
PART
Section twelve
Infectious Diseases

1804 case of spinal TB, from contiguous spread from paravertebral sinuses and prolonged drainage can result.84 Thermal therapy has failed or if the diagnosis is unclear. Incision and drainage should not be done because permanent sinuses and prolonged drainage can result.84

Pleural Effusion

Pleural extrapulmonary TB may occur early after primary infection with MTB and manifest as pleurisy with effusion, or more rarely, it may occur late in postprimary cavitary disease and arise as an empyema.

Tuberculous pleural involvement often causes no symptoms and resolves spontaneously; however, in untreated patients, a 65% relapse rate has been reported, with development of active pulmonary or extrapulmonary TB within 5 years. Dyspnea may occur if the effusion is large, but the effusions usually are small and unilateral. Often the presentation is acute, severe, and indistinguishable from that of a bacterial pneumonia. In the elderly, however, the onset may be more insidious and likely to be confused with congestive heart failure, cancer, or a pulmonary embolus.25

The diagnosis usually is confirmed by microscopic and chemical examination of pleural fluid or pleural biopsy. White blood cell counts usually range from 500 to 2500 cells/mL. The fluid is an exudate with protein usually exceeding 50% of the serum protein, and the glucose may be normal to low. Because there are few bacilli, AFB smears rarely are positive, and cultures grow MTB for only 25 to 30% of patients known to have the disease. Pleural biopsy can confirm the diagnosis in approximately 75% of patients.25

Bone and Joint Infection

Bone and joint TB remains a disease of older children and young adults in developing countries, and it is increasingly a disease of adults in developed countries.25 Skeletal TB presumably develops from reactivation of dormant tubercles originally seeded during stage 2 of the primary infection or, in the case of spinal TB, from contiguous spread from paravertebral lymph nodes to the vertebrae. Generally, spinal TB (Pott's disease) accounts for 50 to 70% of the reported cases; the hip or knee is involved in 15 to 20% of cases, and the ankle, elbow, wrists, shoulders, and other bones and joints account for 15 to 20% of cases.40 Approximately 50% of patients have a previous history or concurrent case of pulmonary TB, and the chest radiograph is normal in appearance in up to one half of the cases.

Patients with Pott's disease may simply complain of back pain or stiffness. Examination may show fever, point tenderness, and decreased range of motion. If the initial radiograph is normal in appearance, the diagnosis may be delayed, allowing the disease to progress. The initial lesion usually spreads to the intervertebral disk and then to the adjacent vertebrae, producing the classic radiographic appearance of anterior wedging of two involved vertebral bodies with destruction of the disk. Early changes of spinal TB can be difficult to detect on plain radiographs and include loss of the “white stripe” of the vertebral end plate subsequent to destruction of subchondral bone. Unfortunately, plain films usually are unable to reveal TB infection until roughly 50% of the vertebra has been destroyed.85 Thus, computed tomography (CT) and magnetic resonance imaging (MRI) scanning should be used when the disease is suspected.25,40 Paraspinal “cold” abscesses develop in 50% or more of cases, with occasional formation of sinus tracts. The abscess can spread the infection up and down the spine, sometimes sparing vertebral bodies along its course, forming the so-called skip lesions.25,85 These skip lesions can easily be missed in imaging the spine for Pott’s disease. The main complication of Pott’s disease is spinal cord compression.40

Medical management includes chemotherapy, modified bedrest, and early ambulation and results in improvement in approximately 90% of patients without neurologic involvement.25 Surgical treatment usually is reserved for patients with neurologic complications.

Renal Disease

The kidney is well vascularized, and hematogenous dissemination to that organ is fairly common. After the typical tuberculous lesions develop within the parenchyma, infection can spread into the calyces, renal pelvis, ureters, and bladder. As a result, tuberculous granulomas, scarring, and obstruction can occur anywhere along the urinary tract.86

The initial presenting signs and symptoms of urinary involvement are nonspecific. Advanced renal disease and destruction may occur before the diagnosis is made. The urinalysis often reveals pyuria, hematuria, and albuminuria. Sterile pyuria is a classic finding in renal TB, but in many cases with this finding, cultures will be positive for other urinary pathogens. The finding of pyuria in an acid urine with no organisms isolated should increase clinical suspicion for TB.40 In one study of the diagnosis of renal TB, AFB stains were found to be 52% sensitive and PCR testing was 96% sensitive.87 Both tests had excellent specificity (97 to 98%). Mycobacterial cultures should be ordered when genitourinary TB infection is suspected.

Complications of renal TB include nephrolithiasis, ureteral obstruction or reflux, recurrent bacterial infections, hypertension, papillary necrosis, renal insufficiency, autoonphrextomy, and, rarely, development of transitional cell cancer.90,97

Male Genital Disease

Male genital TB usually is associated with coexistent renal TB. Spread of infection from the kidney may involve the prostate, seminal vesicles, epididymides, and testes.25 A painless or slightly painful scrotal mass is a typical finding, and the patient may have symptoms of prostatitis, epididymitis, or orchitis.40 Epididymal or prostatic calcifications may be clues to the diagnosis. TB involvement of the seminal vesicles may lead to infertility.97

Female Genital Disease

In women, the disease usually begins with a hematogenous focus in the fallopian tubes. The infection then spreads to the endometrium (in 50%), ovaries (in 30%), cervix (in 5 to 15%), and vagina (in 1%).25 Clinical manifestations may include abdominal or pelvic pain, ascites, infertility, menstrual irregularities, and, rarely, vaginal discharge. An ulcerating mass may be present on the cervix. Genital TB may be confused with ovarian or endometrial cancer, Meigs’ syndrome, vulvar or vaginal ulcer, pelvic abscess, cervicitis, or cervical carcinoma.98
Sexual transmission of TB by persons with active genital TB has been described. Women with genital TB who become pregnant are at increased risk for ectopic pregnancy.

Multisystem Disease

Acute disseminated TB refers to active hematogenous spread of MTB to several organs in the body. The term miliary tuberculosis was first used to describe the pathologic lesions, which resemble small millet seeds. This term is now used as a clinical term referring to the massive dissemination that leads to generalized systemic illness. Miliary TB occurs when the host is unable to contain either a recently acquired or a dormant TB infection. In the past, miliary TB occurred mainly in young children after primary infection; today, it is more common in the elderly and in persons infected with HIV.

In infants and young children, the illness generally is acute and severe. In young adults, the acute illness runs a slower course and usually is less severe. Miliary TB often is a subtle disease associated with alcoholism, cirrhosis, neoplasm, pregnancy, collagen vascular disease, or use of corticosteroids or immunosuppressive medications.

The clinical presentations are varied because of the multisystem nature of miliary TB. Systemic symptoms of fever, weight loss, anorexia, and weakness generally are present. The choroidal tubercle (a granuloma in the choroid of the retina) may represent the only physical finding specific for disseminated TB.

A presumptive diagnosis can be made rapidly if chest radiographs show a miliary infiltrate (Fig. 133-7). Unfortunately, the classic miliary pattern is absent on radiographs in approximately 50% of cases. Routine laboratory tests generally are not helpful. Hyponatremia from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is common and often is associated with meningitis. Panculturing usually has a high yield, and HIV-infected patients may have positive results on blood cultures. Transbronchial biopsy can be performed to obtain tissue rapidly for analysis. Other potential biopsy sites include liver, lymph nodes, and bone marrow.

Mortality rates for miliary TB are higher than for the other forms of TB, with one case series reporting a rate of 21%. The high mortality rate often is caused by delay in treatment, which should always be initiated immediately on the basis of clinical suspicion and not delayed until confirmation of the diagnosis.

A fulminant form of miliary TB may cause the acute respiratory distress syndrome and disseminated intravascular coagulation. In these cases, the addition of corticosteroids (prednisone, 60 to 80 mg/day) is indicated.

Central Nervous System Disease

Approximately 6% of all cases of extrapulmonary TB involve the central nervous system (CNS), and CNS involvement remains a grave consequence of tuberculosis infection. The peak incidence of CNS TB is in newborn to 4-year-old children.

Tuberculous Meningitis

Tuberculous meningitis usually results from the rupture of a subependymal tubercle into the subarachnoid space, rather than from direct hematogenous seeding of the CNS. When it is a complication of miliary TB, meningitis usually develops within several weeks. In children, it is an early postprimary TB event, usually appearing within 6 months. Tuberculous cerebral involvement is most marked at the base of the brain, and vasculitis of local arteries and veins may lead to aneurysm formation, thrombosis, and focal hemorrhagic infarction. The vessels to the basal ganglia most commonly are involved, leading to formation of lacunar infarcts or deficits associated with movement disorders. Involvement of other vessels, such as the middle cerebral artery, may lead to hemiparesis or hemiplegia.

Tuberculous meningitis begins with a prodrome of malaise, intermittent headache, and low-grade fever. In 2 to 3 weeks, a protracted headache develops. Vomiting, confusion, meningeal signs, and coma may follow. Nuchal rigidity may be absent. Diplopia resulting from basilar exudate is present in up to 70% of patients. Hyponatremia may be present because SIADH is common. The CSF cell count usually ranges from 0 to 1500 white blood cells per mL, with a predominance of lymphocytes; however, polymorphonuclear cells may predominate early in the course. CSF protein usually is elevated and CSF glucose typically is low. A single lumbar puncture CSF specimen yields a positive AFB culture result in only 37% of cases, but pooled samples from multiple lumbar punctures yield a positive result in 90% of cases.

The classic triad of neuroradiologic findings in patients with TB meningitis consists of basal meningeal enhancement, hydrocephalus, and cerebral or brainstem infarction. CT or MRI also may reveal rounded lesions typical of evolving parenchymal tuberculomas.

Prognosis is influenced by age, duration of symptoms, and the presence of neurologic deficits. In children, the overall mortality is 13%, and permanent neurologic deficits develop in approximately one half of the survivors. Outcome also is closely linked to the clinical stage at which the disease arises. Complete recovery is the rule in stage 1, wherein the alert patient has no focal neurologic signs and no hydrocephalus. Stage 2 is characterized by confusion and focal neurologic changes, and patients in stage 3 present with stupor or with dense hemiplegia or paraplegia. In contrast with the excellent prognosis for stage 1 disease, approximately one half of patients with stage 3 disease either die or are left with severe neurologic disability.

Treatment starts with a four-drug regimen. INH and pyrazinamide (PZA) reach increased concentrations in the CSF in the presence of inflamed meninges. RIF also crosses the
PART III

- Infectious Diseases

Corticosteroids also are recommended by the CDC. Prednisone, 60 to 80 mg, should be given in a daily dose and tapered over 4 to 6 weeks. Ventricular shunting may be needed if hydrocephalus develops.

Spinal Meningitis

Tuberculous spinal meningitis is a complication of CNS infection that usually originates through hematogenous dissemination from an outside source, although tuberculous meningitis may extend caudally and involve the spine. Local extension of bone or disk TB also has been described. Presenting symptoms and signs result from nerve root or cord compression and may include pain, sensory changes, paralysis, or weakness of bladder or rectal sphincters.

Intracranial Tuberculoma

A tuberculoma usually begins in an area of TB cerebritis as a cluster of microgranulomas, which coalesce into a mature noncaseating granuloma. These space-occupying lesions may cause focal or generalized signs or symptoms, such as tonic-clonic seizures. Involvement of the CNS parenchyma also may be accompanied by meningitis. Imaging reveals either solitary or multiple tuberculomas, usually involving the frontal or parietal lobes. Treatment includes chemotherapy before surgical removal. Corticosteroids may reduce edema and decrease the symptoms. If MTB is discovered at the time of surgery, postoperative chemotherapy may prevent the further spread of the disease.

Gastrointestinal Disease

Gastrointestinal TB infection usually is secondary to hematogenous or lymphatic spread but also may result from swallowed bronchial secretions or direct spread from local sites, such as lymph nodes or fallopian tubes. TB may occur in any gastrointestinal location from the mouth to the anus, but lesions proximal to the terminal ileum are rare. The ileocecal area is the most common site of involvement, producing signs and symptoms of pain, anorexia, diarrhea, obstruction, hemorrhage, and often a palpable mass.

The most common clinical manifestations of gastrointestinal TB are abdominal pain, fever, weight loss, anorexia, nausea, vomiting, and diarrhea. The nonspecificity of these findings as well as those on the physical examination may lead to the misdiagnosis of gastrointestinal TB as appendicitis, intestinal obstruction, or cancer. Approximately 12 to 16% of cases present as an acute abdomen. The signs and symptoms can be so similar to those of other diseases that the diagnosis often is made at surgery. The clinical manifestations of anal TB include fissures, fistulas, and perirectal abscesses. Antimicrobial treatment of gastrointestinal TB is the same as that of pulmonary disease.

Peritonitis

Tuberculous peritonitis may develop from local spread of MTB infection from a tuberculous lymph node, intestinal focus, or infected fallopian tube. In addition, peritonitis can develop from seeding of the peritoneum in military TB or from the reactivation of a latent focus.

The patient with tuberculous peritonitis commonly has pain and abdominal swelling associated with fever, anorexia, and weight loss. Diagnosis may be confounded by the similarity of this disease to alcoholic hepatitis and by the fact that this disease often coexists with other disorders, especially cirrhosis with ascites. Paracentesis is thus essential. The peritoneal fluid is exudative, with a cell count of 500 to 2000 cells per mL. Lymphocytes usually predominate, with rare exceptions early in the process, when polymorphonuclear leukocytes may predominate. AFB smears of the fluid have a low diagnostic yield, with a reported sensitivity of no more than 7%, and the culture result is positive in only 25% of the cases. Peritoneal biopsy often is necessary to confirm the diagnosis. Treatment is the same as for pulmonary TB, with a 6-month regimen.

MANAGEMENT

Initial Emergency Department Management

The most emergent presentation of pulmonary TB is massive hemoptysis, defined as loss of at least 600 mL of blood in 24 hours. Exsanguination rarely occurs, and the major morbidity is due to asphyxiation from aspirated blood. The airway should be secured with a large-diameter (8-mm) endotracheal tube that can accommodate a fiberoptic bronchoscope. The patient should be positioned with the bleeding lung in a dependent position. Selective main bronchus intubation should be considered to allow ventilation of the unaffected lung and to minimize the spread of blood from the affected lung. Emergent consultation for bronchoscopy, surgical resection, or angiography with selective embolization is required. Patients suspected of having active pulmonary TB should be immediately placed in respiratory isolation.

Medical Therapy

Patients suspected of having pulmonary TB whose sputum smears return positive for AFB can be presumptively diagnosed and treated with antituberculous agents. In patients with negative findings on a sputum smear but clinical and radiographic findings consistent with pulmonary TB, it also may be appropriate to initiate treatment for presumptive TB. A few days of therapy with antituberculous agents does not interfere with bacteriologic diagnosis, so severely ill patients with presumed TB should be treated immediately. Local factors, including the prevalence of TB and available resources, help determine the appropriateness of presumptive therapy.
Antituberculosis Medications

Three basic therapeutic principles govern the treatment of TB: (1) any treatment regimen must contain multiple drugs to which the MTB organism is susceptible, (2) the therapeutic agents must be taken regularly, and (3) the therapy must continue for a sufficient period.\(^6\) In clinical practice, the last is the most problematic.

It is estimated that approximately 33 to 50% of patients with TB fail to follow medical recommendations. Patients at higher risk for noncompliance are those with previous treatment failures; substance abusers; patients with mental, emotional, or physical impairment; and those in whom preventive treatment has failed.\(^5\) The most effective strategy to ensure compliance is directly observed therapy (DOT), which is now the preferred practice in the United States.

The medications used to treat MTB generally are divided into first-line and second-line agents\(^6\) (Tables 133-4 and 133-5). Of these agents, 10 have been approved by the U.S. Food and Drug Administration (FDA) for treating MTB. The most

---

* **Dose per weight is based on ideal body weight. Children weighing more than 40 kg should be dosed as for adults.**

**In regimens given in this table, adult dosing begins at age 15 years.**

†† **Dose may need to be adjusted for patients who also are taking protease inhibitors or non-nucleoside reverse transcription inhibitors.**

‡‡ **The drug probably can be used safely in older children but should be used with caution in children younger than 5 years, in whom visual acuity cannot be monitored. In younger children, EMB at the dose of 15 mg/kg per day can be used if there is suspected or proven resistance to INH or Rif.**

§§ **Of note, although this is the dose recommended generally, most clinicians with experience using cycloserine indicate that it is unusual for patients to be able to tolerate this amount. Serum concentration measurements often are useful in determining the optimal dose for a given patient.**

∥∥ **The single daily dose can be given at bedtime or with the main meal.**

\(†\* **Dose: 15 mg/kg per day (1 g) and 10 mg/kg in persons older than 59 years (750 mg). Usual dose: 750–1000 mg administered intramuscularly or intravenously, given as a single dose 5–7 days per week and reduced to two or three times per week after the first 2–4 months or after culture conversion, depending on the efficacy of the other drugs in the regimen.**

\(‡\+ **The long-term use (for more than several weeks) of levofloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. However, most experts agree that the drug should be considered for children with tuberculosis caused by organisms resistant to both INH and Rif. The optimal dose is not known.**

\(§\% **The long-term use (for more than several weeks) of moxifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.**

\(\# **The long-term use (for more than several weeks) of gatifloxacin in children and adolescents has not been approved because of concerns about effects on bone and cartilage growth. The optimal dose is not known.**

EMB, ethambutol; INH, isoniazid; Rif, rifampin.

commonly used first-line agents include INH, RIF, PZA, and ETH. Agents that are used in special circumstances but are not FDA approved for this purpose include rifabutin, levofloxacin, moxifloxacin, amikacin, and kanamycin.

First-Line Agents

INH demonstrates extremely potent early bactericidal activity and can rapidly decrease the patient’s infectivity. The incidence of INH-induced hepatitis is estimated to be 0.6% when INH is given alone, 1.6% when given with other antituberculosis agents (excluding RIF), and 2.7% when given with RIF. The risk increases with age and also with underlying liver disease, alcohol use, and administration during the postpartum period. Another adverse effect is peripheral neuropathy. This is uncommon (less than 0.2%) at standard doses and may be avoided by the co-administration of pyridoxine (25 mg/day). Patients who have conditions associated with neuropathy (e.g., diabetes, HIV infection, alcoholism) and pregnant or breast-feeding women are at increased risk. Supplemental pyridoxine is recommended for such patients.

RIF also demonstrates strong early bactericidal activity. This agent causes orange discoloration of body fluids, including urine, tears, sweat, and sputum. Patients should be warned of this effect before administration of the medication. It is especially important to warn soft contact lens wearers, in whom permanent lens staining may occur. Rifaxentine is a rifamycin derivative with excellent activity against MTB. Its long half-life makes it a good candidate for intermittent therapy regimens (given once weekly). Rifabutin is another rifamycin-like antibiotic that most often is used for treatment or prophylaxis of infections with M. avium complex; however, it also is effective against MTB. This medication generally is used for treatment in patients who do not tolerate RIF or who are taking medications with known adverse interactions with RIF (e.g., antiretrovirals, oral contraceptives, methadone, warfarin).

PZA works against organisms contained in the acid environment of the macrophage. The chief side effect is hepatotoxicity, but this risk is very low at daily doses of 25 mg/kg or less. Polyrhealalgias occur commonly (up to 40% of patients) but usually respond to nonsteroidal anti-inflammatory drugs or aspirin.

ETH is a first-line agent that helps prevent the emergence of RIF resistance during TB treatment. Retrobulbar neuritis can occur, resulting in decreased visual acuity or red-green color blindness. Thus, monitoring of visual symptoms is key to prevention of adverse effects in patients using ETH.

Because of the difficulty in visual testing in small children and infants, ETH should be avoided in these populations, except in the cases of adult-type TB or with INH or RIF resistance.

Fixed-Dose Combination Drugs

Fixed-dose combinations are multiple antituberculosis agents packaged into single tablets. They are useful to prevent monotherapy (e.g., when the patient selectively takes only one of the prescribed drugs) and the emergence of drug resistance. Rifater contains INH, RIF, and PZA. Rifamate contains INH and RIF. These preparations are indicated when DOT is not possible.

Second-Line Agents

Streptomycin was once a first-line anti-TB agent, but increasing resistance rates now limit its usefulness. Streptomycin must be given parenterally and has a peak of action 1 hour after the intramuscular dose. The chief side effects of this potentially teratogenic agent are ototoxicity and nephrotoxicity. Amikacin, kanamycin, and capreomycin also are injectable agents used for drug-resistant TB. As with streptomycin, ototoxicity and neurotoxicity are their major adverse effects. TB strains resistant to streptomycin usually are sensitive to both amikacin and kanamycin, and resistance to these two latter drugs usually is linked.

Cycloserine, ethionamide, and para-aminosalicylic acid (PAS) are oral agents used for treatment in patients with drug-resistant TB when the strain is presumed or known to be sensitive to these agents. Cycloserine also sometimes is used temporarily for patients with acute hepatitis. The main adverse effect of cycloserine is psychosis or seizures (occurring in 3 to 16% of patients). Ethionamide is similar to INH in both structure and toxicity. Major adverse effects of PAS include gastrointestinal distress (most common), hypothyroidism, and hepatitis.

Fluoroquinolones have played a more recent but limited role in the treatment of TB. They are less effective than the first-line agents and are used mainly in the treatment of drug-resistant disease. They also may be used when first-line agents are not tolerated. If they are used singly, resistance may develop quickly. The agents most active against MTB are levofloxacin, moxifloxacin, and gatifloxacin. Because the long-term experience regarding safety and tolerability is greatest with levofloxacin, this fluoroquinolone is preferred. The main side effects are gastrointestinal upset, minor CNS symptoms, and photosensitivity or rash.

**Initial Therapy**

**Adults**

In 2003, the American Thoracic Society, the CDC, and the Infectious Diseases Society of America published a joint statement providing updated evidence-based recommendations for the treatment of TB. The goals of therapy are to rapidly kill large numbers of bacilli (bactericidal activity), prevent emergence of drug resistance, and prevent relapse by eliminating dormant or slowly dividing bacilli (sterilizing activity). There are four basic recommended regimens (Table 133-6). These are used when the organism is known or presumed to be susceptible to INH, RIF, PZA, and ETH. All begin with a 2-month initial phase, followed by a continuation phase lasting 4 to 7 months (total treatment duration of 6 to 9 months). Therapeutic regimens less than 6 months in duration usually are associated with an unacceptably high relapse rate. Dosing frequency varies, ranging from 1 to 7 days per week. There is also variation in the strength of evidence supporting each regimen, depending on the patient’s HIV serostatus. The regimen that is rated as preferred and supported by the strongest evidence (randomized clinical trials) consists of INH, RIF, PZA, and EMB for 8 weeks (5 to 7 days per week), followed by INH and RIF for 18 weeks (2, 5, or 7 days per week). DOT must be used whenever medications are given less often than 7 days per week.

**HIV-Seropositive Patients**

Adequate treatment of active TB in patients co-infected with HIV is critical. It has been observed that immune activation from TB enhances both systemic and local HIV replication and may accelerate the natural progression of HIV infection. Active TB in HIV-infected patients has been associated with increased risk for opportunistic infections and death. TB treatment alone leads to reduction in viral load in these patients. Untreated or inadequately treated TB may result in increased morbidity and mortality, not only from MTB but also from accelerated AIDS. Furthermore, TB can spread rapidly through immunocompromised populations when a source case remains contagious for a prolonged period.

---

*When DOT is used, drugs may be given 5 days/week and the necessary number of doses adjusted accordingly. Although no studies have compared 5 with 7 daily doses, extensive experience indicates this would be an effective practice.**

1. A = preferred; B = acceptable alternative; C = offer when A and B cannot be given; E = should never be given.
2. I = randomized clinical trial; II = data from clinical trials that were not randomized or were conducted in other populations; III = expert opinion.
3. Patients with cavitary lesions on initial chest radiograph and positive culture results at completion of 2 months of therapy should receive a 7-month (31 weeks) regimen of INH, RIF, PZA, and EMB for 8 weeks (5 to 7 days per week), followed by INH and RIF for 18 weeks (2, 5, or 7 days per week). Treatment should be extended an extra 3 months.
4. Not recommended for human immunodeficiency virus-infected patients with CD4 cell counts <100/µL.
5. Options 1c and 2b should be limited to HIV-seronegative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitary lesions on initial chest radiograph. For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.
6. Five-day-a-week administration is always given by DOT. Rating for these regimens is A(III).
Current recommendations for treating MTB in HIV-infected patients are the same as those for patients who are not HIV-infected, with a few important exceptions. The once-weekly INH-RIF dosing for the continuation phase should not be used because of a high relapse rate (17%). The twice-weekly INH-RIF dosing should also not be used in patients with CD4+ counts below 100 cells/µL because of emergence of RIF mono-resistance. Treatment duration should be a minimum of 6 months. The duration should be extended to 9 months if sputum cultures remain positive after the 2-month initial phase of treatment.68

Significant drug interactions between rifamycins used for TB and antiretroviral drugs (protease inhibitors and non-nucleoside reverse transcriptase inhibitors [NNRTIs]) used for HIV infection complicate the treatment of patients with active TB who are co-infected with HIV. These drug interactions are due primarily to changes in the metabolism of the antiretrovirals and the rifamycins secondary to induction or inhibition of the hepatic cytochrome CYP450 enzyme system. The currently available rifamycins are inducers of CYP450, with RIF being the most potent, rifapentine intermediate, and rifabutin the least potent.95 Because all of the protease inhibitors are metabolized by CYP450, coadministration of RIF and the protease inhibitors would cause a marked decrease in the blood concentration of the protease inhibitors, probably reducing their antiretroviral activity as well. For treating MTB in patients who are taking protease inhibitors, rifabutin can be used instead of the other rifamycins. Rifabutin provides good activity against MTB without substantially affecting the effectiveness of protease inhibitors.68

There are major differences in the actions of NNRTIs on CYP450 and the degree to which they are substrates of CYP450; therefore, their interactions with rifamycins cannot be fully summarized as a class.95 However, RIF reduces serum concentrations of all three NNRTIs (delavirdine, nevirapine, and efavirenz). Serum concentrations of NNRTIs must be maintained at an optimal steady state to prevent resistant mutations of HIV. When RIF is used in patients taking nevirapine or efavirenz, the NNRTI dose must be increased. Alternatively, rifabutin can be substituted for RIF without NNRTI dose adjustment. Because of the dramatic reduction in serum concentration, none of the rifamycin preparations are acceptable for patients taking delavirdine.68

When TB treatment is initiated in HIV-positive patients, a paradoxical reaction to medical therapy may develop in some instances. The reaction manifests with development of fever, new or enlarging lymph nodes, or worsening of radiographic disease. It is more common in HIV-infected patients, occurring in 7 to 36% of cases after beginning treatment. Other causes of deterioration, such as treatment failure, must be considered when this reaction is suspected. Severe paradoxical reactions may be managed with a 2-week tapering course of prednisone or methylprednisolone.68

Children and Adolescents

The treatment of adolescents, children, and infants who are culture-positive for MTB is in principle the same as that of adults. Some important differences are recognized, however. In children, active pulmonary TB usually is part of the initial infection. The chest radiograph demonstrates hilar adenopathy and middle or lower lobe infiltrates. Less commonly, the development of “adult-type” infection, which resembles postprimary infection in adults (upper lobe infiltrates, cavitary lesions, sputum production), is seen in this age group. Because the bacillary load of primary infection is lower than with adult-type disease, the recommended regimen for children with primary TB is a three-drug regimen (INH, RIF, PZA) for the 2-month initial phase, followed by INH and RIF for a 4-month continuation phase (for a total of 6 months). For adult-type infection in children, EMB is added to the initial phase. EMB also is added if INH or RIF resistance is suspected. Because it can be difficult to isolate MTB from children, available resistance patterns of the source should be taken into consideration. Visual acuity and color discrimination should be monitored monthly for older children who are treated with EMB. Inability to monitor vision because of young age is not a contraindication to EMB use in adult-type infection or in the case of INH or RIF resistance. Some important points in treating children are presented in Box 133-4.68

Drug-Resistant Tuberculosis

Two types of drug-resistant MTB have emerged as a result of spontaneous mutations. Multidrug-resistant TB (MDR-TB) is defined as TB in which the mycobacteria are resistant to two or more first-line antituberculosis agents. Multidrug resistance may develop when a single drug is added to a failing regimen, an intervention equivalent to giving monotherapy.66 Extensively drug-resistant TB (XDR-TB) is TB characterized by resistance to both first-line and at least three second-line drugs. Patients with TB who are improperly treated (especially with monotherapy) or who are nonadherent to their treatment regimen present a microbiologic milieu likely to offer the drug-resistant strains a selective advantage. When these strains predominate, “acquired resistance” has occurred. Patients with acquired resistance can transmit drug-resistant organisms to previously uninfected (never treated) persons, a process resulting in primary drug resistance.97

Multidrug-Resistant Tuberculosis

Although MDR-TB ultimately can be traced back to suboptimal treatment, it is the transmission of primary drug resistance from person to person that allows rapid dissemination of drug-resistant strains.97 The spread of primary drug resistance is faster when HIV infection is highly prevalent in a population.93,98,99 Because initial TB infection in HIV-infected patients progresses rapidly to active disease, newly infected persons
can quickly become source cases for further transmission of the resistant bacilli. In reports on hospital outbreaks of MDR-TB, more than 90% of patients had co-infection with HIV, and case-fatality rates were as high as 70 to 90%. However, patients without HIV infection demonstrate excellent clinical responses when treated for MDR-TB.

Health care workers should know the prevalence of drug resistance in their community and the risk factors (Box 133-5) for drug resistance in order to identify potential cases. Rapid identification and prompt isolation of these patients, along with other control measures, can reduce nosocomial transmission of MDR-TB to patients and health care workers. Failure to control drug resistance may lead to wide dissemination of MDR-TB and to a public health crisis that physicians must confront without effective medications.

Treatment of drug-resistant TB can be challenging and requires familiarity with second-line agents. For MDR-TB, specialist consultation is essential. A general principle that applies in such cases is to use at least three drugs to which the organism is susceptible and that have not been used previously. In general, one of these medications should be an injectable agent. TB infections with strains that are resistant only to INH can be managed with a 6-month course of RIF, PZA, and EMB. Recommended regimens for some other resistance patterns are listed in Table 133-7.

Extensively Drug-Resistant Tuberculosis

XDR-TB was first recognized in patients co-infected with AIDS in South Africa in 2005. A retrospective analysis of several thousand banked specimens from sources worldwide found that the strain was present in samples every year since year 2000 and that it presented a major threat in Africa, Asia, and areas of the former Soviet Union. In that study, up to 17% of patients in the MDR-TB group actually had XDR-TB. The strain has virulence similar to MTB, and disease does not progress faster in the absence of antibiotics. As resistance to so many antibiotics has developed, however, this strain has become a major threat, especially in patients with AIDS. Most alarming is a recent study that reported as many as 33% of patients with TB co-infected with HIV and MDR-TB had the XDR-TB strain. Mortality rates for this patient population are high, because few alternative drugs exist. The CDC is extremely concerned and has reported a handful of cases in several states. EDs could become a major focus for spread of this disease, because some U.S. EDs are overcrowded and lack procedures, personnel, and space to recognize and isolate potentially infected persons. Reports from Africa have shown that XDR-TB can be transmitted directly to health care workers. Of great concern is the potential for transmission of the disease within the ED by a previously undiagnosed patient with XDR-TB, recently arrived from an endemic country, who presents for treatment for TB-related symptoms or an unrelated condition.

Extrapulmonary Tuberculosis

Evidence from clinical trials, including some randomized controlled trials, indicates that 6- to 9-month regimens provide effective treatment for extrapulmonary TB. An exception is tuberculous meningitis: The CDC recommends 6 to 9 months for bone or joint infection, 9 to 12 months for meningitis, and 6 months for all other forms of extrapulmonary TB.

Corticosteroids

The use of corticosteroids in the treatment of extrapulmonary TB is more common than in pulmonary disease. Corticosteroids may prevent constriction in tuberculous pericarditis and decrease the neurologic sequelae in all stages of tuberculous meningitis, especially if given early in the disease. The CDC strongly recommends corticosteroids for MTB pericardial or CNS infections. Corticosteroids may provide some benefit to children with bronchial obstruction caused by enlarged lymph nodes. In addition, in patients with pulmonary TB, prednisone, 20 to 60 mg/day, may benefit those who continue to experience temperature spiking and to lose weight despite a
good bacteriologic response to appropriate antituberculosis therapy.109

Pregnancy

Treatment of TB during pregnancy poses little risk to the fetus, especially in comparison with untreated disease. INH, RIF, and ETH cross the placenta but have no known teratogenic effects. These three drugs should be used for the initial regimen, followed by a continuation phase of INH plus RIF for an additional 7 months (9 months total). Pyridoxine is recommended for pregnant women receiving INH. The use of PZA in the initial regimen is controversial, mainly because of insufficient data regarding its safety during pregnancy. When PZA is used, the total treatment duration can be reduced to 6 months. Streptomycin may cause congenital deafness and is contraindicated. Kanamycin, amikacin, and capreomycin should therefore be avoided as well. Fluoroquinolones should be avoided because of the potential for arthropathies (as demonstrated in animal models).68 Although these chemotherapeutic agents are present in breast milk, they are not harmful to the infant and are not present in high enough concentrations (approximately 20% of the daily dose) to be therapeutic or preventive.46,68

Surgical Management

The most common indication for surgery is MDR-TB with severe localized disease.107 When optimal medical therapy based on drug susceptibility testing is given preoperatively and postoperatively, the outcome appears to improve.110 In one study of 172 patients who underwent pulmonary resection for MDR-TB, 96% of those with MTB-positive preoperative sputum samples became sputum-negative for MTB after surgery.111 The CDC recommends that surgery be performed after several months of an intensive medication regimen.68 Other indications for surgery may include bronchopleural fistula, massive uncontrolled hemoptysis, extensive bronchostenosis, destroyed lung, solitary nodule, trapped lung, complicated cavity, and empyema.110

Treatment of Latent Mycobacterium tuberculosis Infection

After primary infection with MTB, host defenses usually are able to contain the infection within 2 to 10 weeks. This begins the latent period for MTB infection, when affected persons are not contagious and do not have active disease. Preventive therapy is directed at treating MTB infection during this latent phase to prevent reactivation and development of active disease. Tuberculin skin testing for the presence of latent MTB infection should be performed in persons who are at increased risk for either MTB infection, exposure to infectious cases, or development of active disease (see Table 133-3).28

Treatment of latent MTB infection is indicated for persons in whom the risk for development of active TB outweighs the risks associated with the therapy itself. The risk of INH-induced hepatitis increases with age, but age older than 35 years is not a contraindication to INH administration. In fact, if a patient belongs to a risk group listed in Table 133-3, age is no longer a factor, and treatment for latent MTB infection is warranted.28,79 Persons with impaired cell-mediated immunity, such as young children or immunocompromised patients, may not have positive tuberculin skin test results after initial infection with MTB. Thus, treatment of latent MTB infection should still be considered for such patients if they have experienced a recent (within 3 months) high-risk exposure to MTB.78 Continuation of therapy in such cases should be based on tuberculin skin test results at 3 months after the exposure. Excluding active TB with chest radiographs and clinical evaluation is a critical step before initiation of therapy for latent MTB infection.

Any of four regimens may be used to treat latent MTB infection28 (Table 133-8). The preferred regimen is daily INH for 9 months. The dose is 5 mg/kg in adults and 10 to 20 mg/kg for children, with a maximum of 300 mg/day for both populations. INH also may be given twice daily by DOT. For HIV-positive patients, the recommended regimen is daily INH for 9 months or daily RIF plus PZA for 2 months.79 DOT is recommended for all intermittent-therapy regimens and for persons at high risk for development of the disease, to decrease possible MDR-TB emergence.

### DISPOSITION

Most patients with TB can be managed on an outpatient basis. The ideal situation for the patient with newly diagnosed or suspected TB is to be at home, receiving antituberculosis therapy, with the patient’s contacts receiving preventive treatment. The CDC strongly recommends DOT in order to maximize compliance and completion of therapy.68 The ED discharge instructions should clearly emphasize the importance of adhering to the prescribed treatment regimen and home isolation procedures (avoidance of meeting new contacts). The case must be immediately reported to the health department to ensure that the patient has an adequate source of TB care, that support systems and resources are available to complete the care, and that the patient’s contacts are investigated and screened. Two weeks of treatment is widely accepted as the minimum time to be rendered noninfectious, so long as the patient has been treated with appropriate medications (see also earlier section, “Transmission”).25 Acutely ill or elderly patients may require hospitalization during the first few days of treatment because adverse reactions are common and may occasionally be life-threatening.112 In addition, severely ill patients may require parenteral drug administration. Patients with TB have a high rate of HIV coinfection, and the comorbid illnesses associated with HIV infection, the complex synergy between MTB and HIV disease, and the potentially harmful drug interactions between the antiretroviral agents and the rifamycins may favor inpatient treatment for initial management of these complicated cases.

Hospital admission also is indicated for patients with active MDR-TB. These patients commonly require observation during initiation of therapy because of the complexity of the treatment regimens, the toxicity of the drugs, and the need for close monitoring to ensure adherence to treatment and isolation measures.99 Finally, social issues such as homelessness, presence of infants or immunocompromised persons in the household, substance abuse, and incapacity for self-care may necessitate hospitalization. The recalcitrant patient constitutes a potential threat to public health, and legal measures for involuntary hospitalization may be required.113

■ PREVENTION OF TRANSMISSION IN THE EMERGENCY DEPARTMENT

EDs often care for patients at increased risk for active pulmonary TB, such as those who are homeless, foreign born, recently incarcerated, or chronically ill. Accordingly, ED workers can be at high risk for occupational TB infection. In one county hospital in Los Angeles, 31% of emergency department workers became tuberculin skin test–positive at some time during employment, including 20% of attending physicians, 32% of nurses, and 33% of residents.114 Tuberculin skin test conversion risk was found to be 6% after 1 year of ED employment, 14% after 2 years, and 27% after 4 years. In addition, increased hospital occupancy and ED overcrowding can lead to extended waiting periods for both ED beds and hospital beds.115,116 Some EDs may lack an adequate number of TB isolation rooms.117 Nosocomial transmission risk in the ED setting also is increased, because patients with TB often receive care before the diagnosis is suspected; this risk is particularly high with critically ill patients, who by definition require close, intensive contact with multiple emergency care providers.

Early Identification

For the most effective minimization of infectious exposures among health care workers and other patients, all patients with active pulmonary TB would ideally be placed in respiratory isolation when initially presenting for care. Not surprisingly, this is difficult to accomplish, and delays in identification and respiratory isolation of such patients are frequent. In one ED study of patients with TB, the mean time from ED registration to respiratory isolation was 6.5 hours, and 46% of patients were first isolated on the hospital ward.118 In order to improve the early identification of patients who may have TB, the CDC has recommended screening for TB at triage.29 Triage screening protocols can detect patients with more classic presentations of TB, but reported protocols are only moderately sensitive and somewhat cumbersome.119 Immediate respiratory isolation should be considered for patients with high-risk chief complaints, such as the HIV-positive patient with cough, the person with hemoptysis, or the patient with a history of TB presenting with cough or fever. The best guideline is to initiate respiratory isolation as soon as TB is considered as a possible diagnosis. Masks should be placed on such patients before chest radiographs are obtained. In addition, the development of policies providing for expedited admission to hospital isolation beds and for improved access to local public health facilities may help decrease TB transmission at virtually no cost.117

Isolation and Environmental Control

In addition to triage screening, the use of proper isolation facilities and environmental control measures can help prevent TB exposures. Airflow in the ED plays a central role, and inadequate ventilation has been a contributing factor in many nosocomial outbreaks of TB. Ideally, there should be single-pass airflow from waiting rooms to outside the facility. Within the ED, air should flow from clean areas to less clean areas, rather than vice versa. For EDs that frequently see patients with TB, at least one true respiratory isolation room should be available. The CDC recommends that respiratory isolation rooms have at least 12 air changes per hour and have “negative pressure” (air flows into the room from other ED areas). Other engineering approaches to TB infection control include the use of high-efficiency particulate air (HEPA) filters and upper room ultraviolet light irradiation.29

Personal Respiratory Protection

ED personnel should be familiar with the appropriate use of respiratory protection against TB. Surgical masks (e.g., string-tie masks) should be placed on potentially contagious patients to decrease the release of infectious droplets into the air.29 Air can leak around such masks, however, so they may not adequately prevent health care workers from inhaling infectious droplet nuclei.120 Thus, surgical masks should be used only for source control, not for health care worker protection. More advanced personal respiratory protection devices include N-95 particulate respirators.121 These masks can filter 1-µm particles with at least 95% efficiency and are the preferred masks for health care workers in the ED. They are available in a variety of shapes and sizes and from various manufacturers. HEPA-filtered masks can also be used for health care worker respiratory protection, and these masks were used more extensively before the development of the N-95 masks. Although HEPA-filtered masks are very effective, they are more costly and can make breathing uncomfortable.120

Preventive Therapy after Inadvertent Exposure

Health care workers who are exposed to patients with active pulmonary TB should be referred to their primary care physicians or employee health services for follow-up testing and treatment. Tuberculin skin testing usually is performed within days after exposure to establish whether the health care worker has previously been infected with MTB. If the baseline test result is negative, a follow-up skin test is performed 3 months later to determine whether tuberculin skin test conversion has occurred. Health care workers whose tuberculin skin test result converts to positive (5-mm induration) after an exposure should undergo chest radiography and clinical evaluation to rule out active disease. When active TB infection is excluded, preventive therapy is recommended. The recommendations in Box 133-6 can assist physicians in deciding who should be treated after an exposure.122 For exposures to MDR-TB, expert consultation is advised for selecting an individualized regimen.

Tuberculin Skin Testing

Because all ED personnel are potentially exposed to MTB, a skin test program is essential.29 Skin testing at regular intervals monitors TB transmission among ED personnel and targets staff members who need prophylactic therapy or treatment. Although recommendations for various health care settings depend on the number of TB patients encountered, most ED health care workers should be skin tested every 6 months.29
**Box 133-6 Guidelines for Management after Accidental Exposure to Tuberculosis**

- Healthy persons who remain PPD-negative after a heavy exposure do not require chemotherapy.
- If exposure is discovered immediately, preventive therapy should be started in particularly heavily exposed people who are known to be PPD-negative. If the skin test remains negative after 3 months, therapy can be discontinued.
- Persons who seroconvert to a positive PPD test result after the exposure should take preventive therapy regardless of age.
- Persons without preexposure PPD results who react positively after the exposure should be treated as convertors (see item 3 above).
- Persons known to be PPD-positive before exposure have too slight a risk to warrant preventive therapy.
- Persons who are younger than 35 years of age, have HIV infection, are receiving cancer chemotherapy or long-term corticosteroid therapy, or are otherwise immunocompromised should be considered for preventive therapy, regardless of the exposure.

**Bacille Calmette-Guérin Vaccine**

Although the BCG vaccine has been used since 1921, its overall efficacy, the duration of protective immunity, and the optimal age for administration remain unclear. In the United States, BCG is rarely recommended because of the belief that it may undermine the epidemiologic and diagnostic value of PPD skin testing. However, tuberculin skin tests in patients given previous BCG vaccination usually demonstrate less than 10 mm of induration. Thus, previous BCG vaccination status should be ignored in interpreting skin test results.79

Institutional outbreaks of TB and the emergence of MDR-TB are sparking reassessment of the BCG issue in the United States. Reports of BCG vaccine efficacy range from zero to 80%. One meta-analysis reported the efficacy of BCG vaccine to be approximately 50%.125 Variation in efficacy of the vaccine reported from many studies may be a result of numerous factors. These include differences in strains of BCG associated with the many worldwide production laboratories, study design, and patient age and immunocompetence. A 60-year study in a Native American population showed a 50% reduction in the development of TB in persons receiving BCG vaccine.124 BCG vaccine is currently recommended in the United States only for tuberculin-negative infants and children who cannot take INH and have ongoing exposure to a persistently untreated or inadequately treated patient with active TB, who are continuously exposed to persons with INH- and RIF-resistant TB, or who belong to groups with rates of new MTB infection exceeding 1% per year.123 The World Health Organization recommends that all infants in developing countries receive the vaccine.

One decision analysis suggested that BCG vaccination would be more effective than the current annual testing strategy for health care workers.125 In some European hospitals, health care workers are required to have received BCG. However, the routine use of BCG vaccine in U.S. health care workers is still controversial. What is not controversial is that the vaccine is strongly contraindicated in persons with HIV infection or other immunosuppressive disease. New vaccines against MTB are being researched, including those using attenuated strains of the MTB complex, recombinant mycobacteria, and subunit proteins and DNA vaccines.126

**Key Concepts**

- In the mid-1980s, there was a resurgence of TB cases in the United States. Immigration and the HIV epidemic were important contributing factors. The reemergence of TB has affected both adults and children.
- TB infection starts with primary infection, followed by a latent period in immunocompetent patients. Approximately 10% of infected patients eventually develop reactivation of disease.
- Beyond pulmonary manifestations, a variety of extrapulmonary manifestations may occur including involvement of lymph nodes, pleura, bones or joints, CNS, and genitourinary and gastrointestinal systems.
- TB infection may be more difficult to diagnose in HIV-infected or elderly patients, in whom the clinical presentation often is variable.
- Therapy must be individualized to reflect acuity, sensitivity, system involvement, and underlying conditions. The most commonly used agents are INH, RIF, PZA, and ETH.
- Prevention and screening are fundamental components of any TB control strategy. Patients suspected of having active pulmonary TB should be placed into respiratory isolation as soon as possible.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Historically, bone and joint infections have been described in grim terms. *Aids to Surgery*, written in 1919, notes that “acute infective osteomyelitis ... is a very fatal disease.” With septic arthritis “the patient becomes exhausted from toxaemia or pyemia,” and “ankylosis is the usual most favorable termination.”\(^1\) Advances in diagnostic methods, antibiotic therapy, and surgical techniques have resulted in much better outcomes. In the case of bone infections, the mortality rate has decreased from 15 to 25% in the preantibiotic era to less than 5% today.\(^2\) However, new challenges are being unveiled. The types of infections that are encountered today are evolving, host immunity is decreased in many populations, and management of bone and joint infections is becoming more complex.

Emergency physicians must consider many subsets of patients who are at increased risk for infection, including intravenous drug users (IVDUs), patients with acquired immunodeficiency syndrome (AIDS), postsurgical patients, and patients with iatrogenic immune suppression.\(^3–6\) The emphasis of modern management of bone and joint infections has shifted from preventing sepsis and death to making a prompt diagnosis, initiating treatment, and avoiding the complications and morbidity associated with chronic bone or joint infections.\(^7,8\)

The overall occurrence of bone and joint infections has remained constant over the past 3 decades.\(^9,9\) The incidence of bone infections in hospitalized patients is approximately 1%. In the United States, the incidence of osteomyelitis in children under the age of 13 years is 1 in 5000, while septic arthritis ranges from 5.5 to 12 per 100,000 individuals.\(^10\) Global epidemiologic data regarding community-acquired bone and joint infections in adults vary significantly, with an overall higher incidence in patients of a lower socioeconomic class in developing countries. In the United States, there is no correlation between socioeconomic factors or race and the incidence of bone and joint infections. Bone infections show a bimodal age distribution, occurring most commonly in people under 20 or over 50 years of age. Joint infections have a similar distribution.\(^5,9\) In children, bone and joint infections usually occur in previously healthy individuals, and boys have an increased susceptibility to bone infections, with a male/female ratio of 2 to 3:1.\(^9\) In adults, risk factors can usually be identified in patients who present with either bone or joint infection.

Infectious processes are generally designated as acute, subacute, or chronic. Orthopedic infections are also classified according to the site of involvement and include osseous (osteomyelitis), articular (septic or supplicative arthritis), bursal (septic bursitis), subcutaneous (cellulitis or abscess), muscular (infectious myositis or abscess), and tendinous (infectious tenosynovitis) varieties. The word osteomyelitis literally means inflammation of the marrow of the bone, but the term is loosely used to refer to infection in any part of the bone. A specific definition of chronic osteomyelitis is difficult to find.

From a histologic standpoint, chronic osteomyelitis is diagnosed when areas of necrotic bone are identified. Chronic osteomyelitis may also be defined as a bone infection lasting for more than 10 days or infection that fails a normal course of antibiotic therapy.

Septic arthritis is defined as an infection of a joint by bacterial or fungal organisms. Bacterial arthritis is sometimes called pyogenic or suppurative arthritis. Several common infectious processes can result in a sterile, secondary inflammation of joints, termed reactive arthritis. Reactive arthritis is not classified as septic arthritis because there are no infecting microorganisms within the joint. This type of arthritis is far more common than septic arthritis. Commonly, a reactive arthritis occurs after infection with human parvovirus, rubella, chickenpox, and other viruses,\(^11,12\) although reactive arthritis can also develop after group A streptococcal infection.

There are many classification systems for osteomyelitis based on the condition of the host, functional impairment caused by the disease, site of involvement, and extent of bony necrosis. For the emergency physician, the most practical way to classify osteomyelitis is based on etiology as described by Waldvogel. Waldvogel divides osteomyelitis into two broad categories: hematogenous osteomyelitis and osteomyelitis secondary to a contiguous focus of infection.\(^2,13\) Osteomyelitis from a contiguous focus is further subdivided based on the presence or absence of vascular insufficiency. The latter is often secondary to trauma, surgery, or insertion of a prosthetic joint or other hardware into bone. Recognition of the etiologic mechanism of osteomyelitis assists in the interpretation of diagnostic imaging examinations and helps to guide management.

Septic arthritis usually results from hematogenous migration of bacteria into the joint. Less commonly it is caused by direct inoculation of bacteria from trauma or joint aspiration, or from infected foreign material such as a prosthesis. It is important to consider that septic arthritis may occur concomitantly with osteomyelitis, with infection spreading from bone to joint, and vice versa.
Bones are composed of an outer shell, or cortex, of compact bone and an inner framework of trabeculae, called cancellous, spongy, or medullary bone. On a microscopic level, compact bone is composed of structural units called haversian systems that are made up of concentric rings of osteocytes. Osteocytes synthesize and maintain the bony matrix. The central haversian canals run parallel to the long axis of the bone and contain the blood supply and reticular connective tissue for the haversian system. Cancellous bone consists of irregular branching trabeculae that enclose marrow cavities.

Long bones consist of a diaphysis, or shaft, and two ends, called epiphyses, which articulate with other bones. The metaphysis is the region between the diaphysis and epiphysis (Fig. 134-1).

Joints are enclosed within a two-layered capsule. The outer layer is dense fibrous tissue, interwoven with ligaments and the periosteum of articulating bones. The inner layer is the synovial membrane, consisting of secretory cells sitting on a loose fibrous stroma. In some joints, such as the shoulder, hip, and knee, the synovial membrane extends beyond the epiphysis and attaches to the metaphysis. This anatomic relationship allows bacteria to spread from the metaphysis into the joint.13–16

Osteomyelitis begins when bacteria invade the medullary space of bone. The metaphysis is the first to be infected due to the slow flow of blood in the sinusoidal blood vessels. Acute inflammatory cells migrate to the area, causing edema, vascular congestion, and small vessel thrombosis. Acutely, pus spreads into the haversian and vascular channels, raising the intraosseous pressure and compromising blood flow to the bone. Infection may proceed laterally through Volkmann’s canals, which are small channels that run perpendicularly to the haversian system, and reach the subperiosteal space. Eventually, blood supply to both the medullary canal and the periosteum are compromised, leading to areas of necrotic bone called sequestra. The presence of necrotic bone is the hallmark of chronic osteomyelitis. Since there is significantly reduced blood supply to this necrotic bone and ischemic tissue, bacterial infection is very difficult to eradicate with medication alone and chronic osteomyelitis often requires both surgery and antibiotic therapy.

The variation of the blood flow at the metaphyseal/epiphyseal junction results in the variety of pathologic features of hematogenous osteomyelitis among the different age groups. This is partly due to the differences in vascular anatomy as the skeleton ages.

In neonates and infants, arterial vessels from the metaphysis perforate the epiphyseal growth plate and terminate in the epiphysis in venous sinusoids. This communication allows osteomyelitis to advance readily from the metaphysis to the epiphysis and adjacent joint space, leading to septic arthritis. Cortical bone in neonates and infants is thin and loosely attached to the underlying bone. It is composed primarily of woven bone, which allows for the release of pressure caused by the infection and also allows the infection to rapidly spread in the subperiosteal region. Because of these structural char-
characteristics of bone in neonates and infants, pressure-related
cortical infarction does not usually occur and sequestra are not
created. Infection remains trapped in the subperiosteal region
and eventually leads to subperiosteal abscess formation. The
periosteum is stimulated and vigorous formation of new peri-
osteum occurs. This new growth of the periosteum is called
an involucrum.

After the first year of life there is no longer a vascular con-
nection between the metaphysis and epiphysis. The metaphy-
seal arteries end in loops that abut the growth plate. The
epiphysial growth plate is avascular and inhibits the spread of
infection to the epiphysis and joint. The infection spreads
laterally via Volkmann’s canals, breaks through the cortex, and
lifts the loose periosteum to form a subperiosteal abscess.17

In the adult, after the closure of the epiphyseal plate and
resorption of the growth plate, anastomoses form between the
metaphyseal and epiphyseal blood vessels, and infection can
once again spread from metaphysis to epiphysis and eventu-
ally into the synovium and joint space.14,18 In addition, the
periosteum is firmly attached to the underlying bone, limiting
subperiosteal abscess formation. Decreased osteoblastic activ-
ity in adults limits involucrum formation. However, infection
can erode through the periosteum, forming a draining sinus
tract19 with more extensive longitudinal diaphyseal spread.
The devascularized weakened bone is prone to fractures.7,13,19

If osteomyelitis proceeds unchecked, ischemic segments of
bone may detach from surrounding bone. These separated
sections are called sequestra and occur only in advanced or
chronic osteomyelitis. Bone infection may progress into the
adjacent soft tissues with abscess formation. The sequestrum
can migrate outward from the medullary space through a corti-
cal opening (cloaca) and then to the skin surface through a
fistula.

Hematogenous osteomyelitis develops when blood-borne
bacteria are deposited in bone. This is most common in chil-
dren and in adults with vertebral osteomyelitis. A number of
local and humoral factors play a role in determining whether
bacteremia progresses to significant skeletal infection. Normal
bone is highly resistant to infection. Three main factors con-
tribute to the pathogenesis of osteomyelitis: the virulence of
the infecting organism, the underlying immune status of the
host, and the type, location, and vascularity of the bone. Some
sites in the skeletal system are more likely to become colo-
nized by bacteria. Bones containing slow-moving venous
systems or venous sinuses, such as the metaphyses of long
bones and the vertebral bodies, have increased susceptibility
to hematogenous osteomyelitis. In the metaphysis, a relative
lack of phagocytic cells in the venous capillaries and sinuses
may further predispose to infection. In the synovial mem-
brane, the existence of a deep venous plexus that also has
sluggish blood flow may invite deposition of bacteria.

*Staphylococcus aureus*, the most common cause of both hema-
togenous and contiguous osteomyelitis, has developed mecha-
nisms to increase bone adherence, increase proteolytic activity,
and increase resistance to host defense mechanisms. A number
of extracellular and cell-associated factors contribute to the
enhanced virulence. In the early stages of osteomyelitis or
septic arthritis, *S. aureus* expresses microbial surface proteins
that promote adherence to many components of the extracel-
larular matrix proteins. In joints, the synovium lacks a basement
membrane, allowing bacteria to penetrate and bind to the ex-
posed surfaces of articular cartilage, bone, and even pro-
thetic devices. The adherence of bacteria such as *S. aureus*
is facilitated by expression of adhesins, which link to a glycopro-
tein called fibronectin. Fibronectin is found in bone and
synovium and can coat artificial surfaces such as prostheses. *S.
aureus* has been shown to produce fibronectin-binding adhes-
ins that encourage the attachment of the bacteria. A biofilm is
rapidly formed, and this promotes adherence of other bacteria
and colony formation.7,13,20 Biomaterials, including the metal
and plastic components of prosthetic joints, acrylic bone
 cement, devascularized bone graft, and synthetic bone substi-
tutes, cause local immune impairment and allow nonpatho-
genic skin flora such as coagulase negative staphylococci to
become significant pathogens. Proteolytic enzymes that are
present in noninfected joints are normally inhibited; however,
this inhibition is lost in the face of infection, enabling the
invading bacteria to persist. Finally, *S. aureus* can surmount
host defense mechanisms at both the cellular and matrix
levels. For example, *S. aureus* can increase expression of
protein A. This is covalently bound to the bacterial cell wall
and binds to the Fc portion of immunoglobulin G on neutro-
phils that interfere with the opsonization and phagocytosis of
*S. aureus*, leading to an increase in virulence.7,11,22

The humoral immune response to bone or joint infection is
usually well developed by the time the infection is clinically
apparent. B lymphocytes sense bacterial antigens and release
antibodies, and an antigen-antibody complex is formed at the
site of infection. Via the complement cascade, bacteria are
destroyed by neutrophils or macrophages. Bacterial toxins may
be destroyed directly by bound antibody.8,13,20,23

Tissue injury in bone or joint infections can occur by several
different mechanisms. Direct tissue destruction by invasive
bacteria is the initial insult. After this, microabscesses and
epiderm and edema in infected tissues may lead to vascular occlusion
and ischemic necrosis, which is most damaging in the venous capi-
laries of the metaphysis, where no collateral blood vessels exist
to compensate for ischemic injury. If immune complexes
become embedded in the bone or cartilage matrix, a prolonged
inflammatory response can occur even after the primary infec-
tion has been cleared. This is particularly a problem in joints,
where articular cartilage can be destroyed. A final type of tissue
injury caused by infection is abnormal synthesis of bone or
joint matrix and cells. Abnormally synthesized bone or carti-
lage may be structurally unsound and function poorly.13,23

Hematogenous spread causes almost all cases of osteomy-
elitis in children and in the subset of adults who have vertebral
osteomyelitis. In the appendicular skeleton of adults, osteo-
myelitis occurs more commonly by either spread of the patho-
gen from a contiguous source of infection or direct implantation.

The direction of contamination for contiguous focus osteomy-
elitis is from the soft tissues inward into the bone, and the
pathogen is disseminated via haversian and Volkmann’s canals
to the bone marrow. This is the opposite of hematogenous
osteomyelitis, where infection starts in the medullary bone
and progresses outward to involve the surrounding structures.

The most common sites of contiguous focus osteomyelitis are
in the foot and hand. Other common sites affected by this
mechanism include the skull, maxilla, and mandible. Head
and neck osteomyelitis is usually caused by sinus disease and
odontogenic infections.

Most infections caused by direct implantation of bacteria
into bones are caused by deep puncture wounds and tend to
occur in the hands and feet. Animal bites are another cause of
infections that can result in osteomyelitis. Although cats
account for only 10% of animal bites, significant infection
results from 20 to 50% of cat bites versus only 5% of dog bites.
Most human bite injuries are related to fist fights, with con-
 tamination of the metacarpophalangeal joints and metacarpals
with secondary infection. Osteomyelitis from direct implanta-
tion of pathogens is seen commonly with open fractures, and
can occur during surgical instrumentation. Artificial joints
and other implanted surgical materials can serve as sites for colo-
nization of bacteria.24,25
In septic arthritis, unless there is direct injection of bacteria into the joint, infection occurs first in the synovium and then extends into joint fluid, and finally to articular cartilage. The synovial membrane responds to infection by increasing synovial fluid production, resulting in a large joint effusion. Septic arthritis is a closed space infection, and increasing pressure in the joint contributes to a decreased rate of exchange of solutes across the synovial lining. The resultant slow diffusion of nutrients across the synovial membrane may limit the growth of bacteria and may cause bacteria to enter a dormant state. Dormant bacteria has increased resistance to levels of antibiotics that would normally be bactericidal. Even small numbers of bacteria in the joint space can elicit a profound and persistent inflammatory and immune response. Bacteria can be cleared from the joint, resulting in a sterile-appearing inflammatory response. In animal models, the injection of isolated bacterial DNA into joints can produce a marked inflammatory arthritis. These types of observations have led to the hypothesis that some forms of arthritis, previously believed to be sterile or reactive, may in fact be due to an initial infection of the joint with small numbers of microorganisms followed by clearance of these microorganisms with a prolonged inflammatory response.

The most important factor that determines morbidity from septic arthritis is the degree of articular cartilage destruction. Once destroyed, hyaline (articular) cartilage cannot be replaced. As part of the response to infection, synovial cells and polymorphonuclear leukocytes release lysosomal enzymes into joint fluid. These enzymes contain collagenase and elastase, both of which degrade cartilage. Cytokines also seem to play a key role in the release of metalloproteinases and other harmful enzymes. Other structures that are enclosed within or adjacent to the synovium, such as bursae, tendons, and bone, may become damaged in septic arthritis.

ETIOLOGY AND MICROBIOLOGY OF BONE AND JOINT INFECTIONS

The pathogenic organisms in osteomyelitis are numerous. The organism responsible for most types of osteomyelitis is S. aureus, which has a number of mechanisms to resist host response, as discussed above.

Certain types of trauma may predispose patients to osteomyelitis by particular bacteria. Patients who are wounded or sustain open fractures in fresh water are susceptible to infection with the gram-negative bacillus Aeromonas hydrophila. People who are bitten, particularly by dogs and cats, are at risk for developing osteomyelitis from Pasteurella multocida. In the IVDU population, S. aureus is the most likely cause of infection, followed by Pseudomonas species. Pseudomonas aeruginosa is also an important cause of osteomyelitis in puncture wounds, postsurgical wounds, and in patients with sickle cell anemia. Osteomyelitis caused from human bites is most common in the hand and involves human oral flora such as Streptococcus anginosus, Fusobacterium nucleatum, and Eikenella species.

Certain underlying disease states predispose a patient to acquiring bone and joint infections. These conditions include diabetes mellitus, sickle cell disease, AIDS, alcoholism and IVDU, chronic corticosteroid use, preexisting joint disease, and other immunosuppressed states. Common to most of the diseases that predispose to bone and joint infections are a decreased ability to mount an inflammatory and immune response, impaired bacterial killing, and poor vasculature. Another subset of patients who are susceptible to bone and joint infections are postsurgical patients, especially those who have had prosthetic devices implanted. In children, an association may exist between prior respiratory illness or minor extremity trauma and the development of bone and joint infections.

Although most serious bone and joint infections are bacterial, on rare occasions, viruses, fungi, and parasites may be the responsible pathogens. The microbiology of osteomyelitis and septic arthritis is a function of several host and environmental factors. As has been described, age is an important variable in determining the type of bacteria that cause bone and joint infections. A patient’s living environment also has some role in determining the incidence of bone and joint infections. For example, people living in crowded conditions where tuberculosis is prevalent are at increased risk for tubercular bone and joint infections. Elderly patients in hospitals and institutions may be more susceptible to infections with gram-negative bacteria. A summary of the organisms that cause osteomyelitis and septic arthritis is given in Table 134-1. The following points deserve special mention:

1. In all age groups except neonates, S. aureus is the leading cause of osteomyelitis. It also accounts for more cases of septic arthritis than any other bacterium. In neonates, group B streptococci, Escherichia coli and other gram-negative coliforms, and Staphylococcus epidermidis are the most common pathogens in bone and joint infections.

2. Before the introduction of the vaccine, Haemophilus influenzae type B caused up to 34% of septic arthritis and 13% of osteomyelitis in children under 2 years of age. However, since the introduction of the vaccine, H. influenzae type B has essentially disappeared as a pathogen in hematogenous osteomyelitis and septic arthritis among vaccinated children. Another gram-negative cocobacillus within the Neisseriaceae family, Kingella kingae, has become more common than Haemophilus in causing bone and joint infections in children. K. kingae can be part of the normal flora of the nasopharynx, which, like H. influenzae, can be spread hematogenously to bones and joints. It is a fastidious organism and may be mistaken for Haemophilus or Neisseria species.

3. Gonococcal arthritis is the most common type of monoarticular septic arthritis in individuals under 30 years of age.

4. In elders, gram-negative bacteria account for a higher percentage of cases of bone and joint infections than in younger people.

5. Methicillin-resistant Staphylococcus aureus (MRSA), methicillin-resistant S. epidermidis, and vancomycin-resistant enterococci have emerged as a significant microbiologic problem in the past decade. Multiresistant enterococci pose the greatest potential danger in that no currently available regimen is reliably bactericidal against such organisms.

A typical case of hematogenous osteomyelitis or septic arthritis is caused by a single strain of bacterium. Polymicrobial infection is more likely to occur in diabetic foot osteomyelitis, post-traumatic osteomyelitis, and chronic septic arthritis. Overall, polymicrobial osteomyelitis occurs in 36 to 50% of reported cases. Anaerobic bacteria can complicate polymicrobial infection and may be present in bone and joint infections more often than is commonly recognized. In chronic osteomyelitis, anaerobic bacteria may be present in up to 40% of cases. Culture techniques that are inadequate for isolating anaerobic bacteria may lead to underreporting of infections caused by these agents.

Pseudomonas aeruginosa has been reported as a cause of cervical spine osteomyelitis in injection drug users and lumbar spine osteomyelitis in patients with urinary catheters in place for long periods of time. Pseudomonas colonizes the rubber and
plastic inserts in footwear and is therefore seen in soft tissue infections and osteomyelitis of the foot after a puncture wound. Patients in whom prosthetic devices are implanted during orthopedic surgery are also at risk for Pseudomonas bone and joint infection.15,34,41

Tuberculosis may occur in bones and joints. The two most common forms of skeletal infection are vertebral osteomyelitis (Pott’s disease) and tubercular arthritis. The spine is affected in half of cases of tubercular skeletal infection. The arthritis of tuberculosis is a chronic, low-grade inflammatory process that resembles rheumatoid arthritis more than acute septic arthritis.36,37,42,43

Fungal infection is a complication of catheter-related fungemia, the use of injection drugs contaminated by Candida species, and prolonged neutropenia. Fungal organisms are responsible for less than 1% of cases of osteomyelitis, but the number of reported cases is increasing. Candida osteomyelitis occurs through hematogenous spread or as a postoperative wound infection. Fungal bone infection is indolent and may go through periods of activity and remission.44,45 Aspergillus has been reported to cause osteomyelitis in vertebral, hip prostheses, and ribs. In adults the infection is hematogenous. In children Aspergillus osteomyelitis is most common in those with prior granulomatous disease and spreads from a primary pulmonary infection. Blastomyces and Cryptococcus are two other fungi that may become disseminated and infect the skeleton.44,46 Treatment of these infections is difficult, and therapy needs to be individualized against the specific organism.56

Patients with human immunodeficiency virus (HIV) are predisposed to a variety of common and opportunistic pathogens. Although S. aureus is still the most likely cause of bone and joint infections in patients with AIDS, fungal and other atypical organisms should be considered. One unusual, but particularly characteristic, form of osteomyelitis in HIV-positive patients is bacillary angiomatosis. This infection is caused by a gram-negative rickettsia-like organism that frequently causes osteolytic bone lesions.35

Concurrent treatment for Chlamydia trachomatis should be given in patients with suspected N. gonorrhoeae septic arthritis. Bone and joint infections with H. influenzae are now rare in vaccinated children; however, if the Gram’s stain is suggestive of H. influenzae, empirical treatment should be started. Fluoroquinolones are not recommended for use in children. AC, amoxicillin-clavulanate; Alt, alternative antibiotics; APAG, antipseudomonal aminoglycoside; AP Ceph, antipseudomonal cephalosporin (ceftriaxone, cefotaxime, cefamandole, cefotizoxime, ceftazidime, moxalactam, etc.); Clind, clindamycin; FLQ, fluoroquinolone; MRSA, methicillin-resistant Staphylococcus aureus; PRP, penicillinase-resistant penicillin (oxacillin, nafcillin, methicillin, amoxicillin-clavulanate); TS, trimethoprim-sulfamethoxazole.
### CLINICAL FEATURES OF OSTEOMYELITIS

#### Diagnosis

**History and Physical Examination**

The symptoms and signs of osteomyelitis in adults are predictable, although not always present. The predominant symptom of osteomyelitis is pain over the affected bone. Patients with osteomyelitis often present with fever and rigors and may appear toxic. Fever appears to be present more commonly in children. Systemic complaints of headache, fatigue, malaise, and anorexia are often reported. However, these findings are inconsistently present and are less likely with chronic osteomyelitis. In children with lower extremity osteomyelitis, a sudden limp or inability to weight bear may be reported. Localized warmth, swelling, and erythema may be reported. A careful review of the patient’s past medical history is especially important in order to identify risk factors that may predispose to bone infection.

The physical examination findings of osteomyelitis are fairly specific. Palpation of the involved bone usually elicits point tenderness over the infected segment. Palpable warmth and soft tissue swelling with erythema may be present, but these findings are variable. Because osteomyelitis has a propensity to occur in the metaphyses of long bones, it is often difficult to distinguish infection in bone from infection in the neighboring joint. A “sympathetic” effusion in the adjacent joint may develop in some patients with osteomyelitis even when the joint is not infected. In chronic advanced osteomyelitis, the involucrum or sequestrum may be palpated, and sinus tracts that drain through the skin may be noted.

#### Diagnostic Strategies

**Laboratory Data and Diagnostic Imaging.** Bone biopsy and culture are the gold standard and definitive test used to confirm the diagnosis and guide treatment of osteomyelitis. Biopsy may be performed with an open procedure or by fine-needle aspiration.

Laboratory data in patients with osteomyelitis are not diagnostic and can only suggest osteomyelitis. The white blood cell (WBC) count is often, although not always, elevated, with typical values ranging from normal to 15,000 cells/mm³. The erythrocyte sedimentation rate (ESR), a nonspecific measure of inflammation, is more helpful than the WBC count. The ESR represents the rate at which red blood cells fall when anticoagulated blood is placed in an upright tube. When an inflammatory process is present, the high proportion of fibrinogen in the blood causes the red blood cells to form stacks, called rouleaux, which settle faster. This is a sensitive marker for bone infection; many series report elevated ESRs in more than 90% of patients who have confirmed osteomyelitis. The mean ESR in one large pediatric review was 70 mm/hr. Fewer than 8% of patients with osteomyelitis will have an ESR less than 15 mm/hr. An elevated ESR in the presence of appropriate physical findings should alert the emergency physician to pursue the diagnosis of osteomyelitis, but a normal or slightly elevated ESR does not eliminate the diagnosis. Other inflammatory conditions such as cellulitis can cause an elevated ESR, although the degree of elevation of ESR is often higher with osteomyelitis. C-reactive protein (CRP), another nonspecific marker of inflammation, is produced by the liver and by adipocytes in response to interleukin-6 and may have some use in evaluating patients with bone infections. CRP increases within the first 24 hours of infection, peaks within approximately 48 hours, and is usually normal within 1 week of therapy. In children presenting with osteomyelitis, it has been shown that ESR was elevated in 92% and CRP was elevated in 98%, and the WBC count was elevated in 35%. These tests have a high positive predictive value, and elevated values should increase suspicion of this diagnosis. However, normal values of these nonspecific inflammatory markers cannot be used to rule out the diagnosis of osteomyelitis. The CRP may be a better early indicator of disease, but the ESR is most valuable in following response to treatment. Typically, the ESR falls steadily as osteomyelitis resolves, and increases should it recur.

The diagnosis of osteomyelitis in the emergency department (ED) is almost always made by skeletal imaging. Since conventional radiography is readily available, relatively inexpensive, and useful in differentiating infection from trauma and tumors, it remains the initial imaging test of choice for suspected osteomyelitis. In addition, plain radiography is often a helpful adjunct to secondary imaging studies. Unfortunately, radiographic evidence of osteomyelitis lags behind the clinical picture, and less than one third of patients have abnormalities on plain radiographs in the first 7 to 10 days after the onset of symptoms. The characteristic early findings on the plain radiograph in osteomyelitis are lucent lytic areas of cortical bone destruction (Fig. 134-2). However, lucency is not detected on radiographs until approximately 50% of bone mineral is lost, and this often takes up to 2 weeks from the onset of infection. Soft tissue edema, deep soft tissue swelling, distorted fascial planes, and altered fat interfaces may be present within 3 to 5 days from the onset of infection and can serve as a clue to osteomyelitis in the underlying bone. Periosteal reaction is another early sign. It may appear on radiographs as hypertrophy or elevation of the periosteum (involucrum) (Fig. 134-3). These early periosteal changes are more commonly seen in children than in adults. In advanced disease, the lytic lesions are surrounded by dense, sclerotic bone, and sequestra may be noted. Because radiographic resolution may lag behind clinical resolution, radiographs are also not helpful in tracking the course of osteomyelitis. Radiographs have more utility in the diagnosis of chronic osteomyelitis. By 28 days from the onset of disease, 90% of the plain radiographs are positive. (See Figs. 134-2 and 134-9.)

Radionuclide skeletal scintigraphy (bone scanning) is more sensitive than plain radiographs in the early diagnosis of osteomyelitis, especially in the presence of prosthetics or other hardware. Radionuclide scans can detect osteomyelitis within 48 to 72 hours after the onset of infection. A radioactive tracer is injected into the bloodstream and given time to bind or accumulate in body tissues. A gamma camera or collimator is used to sense released radioactivity, and an image is created that is evaluated for increase or decrease in expected uptake of the radionuclide.

For nuclear imaging, the radiopharmaceutical of choice for skeletal scintigraphy, both in the ED and as an inpatient, is technetium methylene diphosphonate (99mTc MDP). Technetium-labeled diphosphonates bind to the hydroxyapatite crystals in the bone matrix and therefore identify areas of increased osteoblastic activity. Consequently, this technique is highly sensitive for the early detection of acute osteomyelitis. The standard 99mTc MDP scan is a three-phase process. After injection of the 99mTc MDP, images are obtained within 60 seconds. This “radionuclide angiogram” illustrates the relative blood flow to the area of concern. The second phase involves imaging of the “blood pool” of 99mTc MDP at 5 to 15 minutes after injection. The third phase is the delayed or static image that is obtained 2 to 4 hours after injection. Areas of osteomyelitis show increased uptake on all three phases of 99mTc MDP scintigraphy.
Figure 134-2. Radiographic progression of acute osteomyelitis. **A**, Soft tissue swelling at both the medial and lateral aspects of the ankle with a moderate-sized effusion (August 2, 2006). **B**, Large ankle effusion with extensive soft tissue swelling. There is complete loss of the tibiotalar joint space as well as widening of the medial joint space, suggesting chondrolysis. There are lucent areas in the distal tibia and fibula, suggestive of hyperemia, and the talus is diffusely sclerotic (September 11, 2006). **C**, Increased erosion of the medial aspect of the talar dome with increased joint effusion (October 12, 2006). **D**, Talar bony destruction with demineralization involving all of the osseous structures. There is also a small joint effusion (January 2, 2007). **E**, Avascular necrosis of the talus is present, as is destruction of the articular surfaces of the tibia and talus consistent with chronic osteomyelitis. There is diffuse osteopenia as well as loose bodies within the joint (April 19, 2007). **F**, There is continued irregularity of the articular surface of the tibia as well as collapse of the talus. Loose bodies are still present within the joint, and there is a persistent joint effusion and soft tissue swelling (June 14, 2007). (Courtesy of Thomas Egglin, MD, Department of Diagnostic Imaging, Rhode Island Hospital, Brown University.)
based on $^{99m}$Tc MDP three-phase scanning. Figure 134-5 shows a positive $^{99m}$Tc MDP scan.

The $^{99m}$Tc MDP scan is a sensitive test for osteomyelitis in patients who have no existing bone abnormalities. Most series report a sensitivity of greater than 90% with the three-phase scan. Lower sensitivities are found in cases of neonatal osteomyelitis. False-negative scans are possible if pressure and edema in an area of active osteomyelitis prevent vascular delivery of the radionuclide. The resulting “cold spot” may actually signify an area of aggressive active osteomyelitis. False-negative scans may also occur if the patient has been receiving antibiotic treatment before presentation. The specificity of a $^{99m}$Tc MDP bone scan is not as high as its sensitivity. False-positive scans may result from trauma, surgery, tumors, or chronic soft-tissue infections. Simple cellulitis does not usually produce a false-positive bone scan, since the radionuclide is cleared from soft tissues prior to acquisition of the delayed (third phase) images. Any process that encourages inflammation and new bone formation can result in increased uptake of radionuclide. The false-positive rate for bone scans is as high as 64% in various case series.$^{33,56,58}$ A four-phase $^{99m}$Tc MDP study with an additional image at 24 hours may further improve specificity, because the amount of activity within the lesion theoretically continues to increase with time.$^{58}$

Other radioisotopes, such as gallium citrate, indium oxine, and hexamethyl-propyleneamine oxime, may be used in skeletal scintigraphy as adjuncts to $^{99m}$Tc scans, and various combinations of these tests are done to improve specificity. These scans are more expensive, take longer to complete, and entail more radiation exposure than technetium scans. These disadvantages greatly limit the use of other bone scan radioisotopes in the ED diagnosis of osteomyelitis.

In the past decade there has been a movement away from skeletal scintigraphy in the diagnosis of osteomyelitis. There is a significant radiation burden associated with scintigraphy, and recent recommendations are that children suspected of having acute osteomyelitis should have magnetic resonance imaging (MRI) rather than a bone scan.$^{58}$

Computed tomography (CT) may be useful in the diagnosis of osteomyelitis. CT is most commonly used to detect and define areas of possible infection in bones with complex anatomy that is difficult to visualize on plain radiographs and bone scans. The bony cortex is particularly well seen on CT, and involucrum and sequestrum formation is easily identified. The sternum, vertebrae, pelvic bones, and calcaneus are far better imaged with a CT scan than with plain radiographs. Osteomyelitis appears as rarefaction, or lucent areas, on the CT scan images. Gas may be seen in bony abscess cavities. The limitation of CT scans for early diagnosis of osteomyelitis is the same as that for plain radiographs in that the disease must be present for more than a week for changes to be apparent. An important role of a CT scan in osteomyelitis is to help localize bony lesions that have been found with other imaging modalities. The CT scan can guide the surgeon in débridement and resection of infected bone and in choosing a site for diagnostic bone biopsy.$^{56,58}$

The use of bone scans and CT for detection of osteomyelitis in the ED is decreasing as the availability and image quality of MRI improves while its cost decreases. The anatomic resolution of both CT and MRI is far superior to that of bone scans and plain radiographs. Both can reveal edema and the destruction of the medulla, as well as any periosteal reaction, cortical destruction, articular damage, and soft-tissue involvement, even when conventional radiographs are still normal. While the presence of ferromagnetic material is a contraindication to MRI, most materials used in orthopedics, such as titanium and chrome cobalt, do not interfere with this imaging modality.
MRI uses a combination of spin-echo $T_1$-weighted and $T_2$-weighted images, short tau inversion recovery (STIR) images, and fat-suppressed $T_2$-weighted images. Osteomyelitis produces a diminished intensity of the normal marrow signal on MRI $T_1$-weighted images and a normal or increased signal on $T_2$-weighted images (Fig. 134-6). The images obtained by MRI in acute osteomyelitis are the result of the medullary space edema and exudate formation. MRI findings are often evident before a positive result is seen with skeletal scintigraphy because of the earlier detection of bone marrow involvement. While the interface between normal and abnormal marrow is indistinct, administration of gadolinium leads to enhancement of the involved viable marrow and helps to distinguish devitalized from normally perfused bone. Gadolinium becomes localized in areas of increased vascularity and blood flow and helps to distinguish soft tissue infections such as abscesses and cellulitis from osteomyelitis. Most radiologists recommend gadolinium contrast MRI when osteomyelitis is the leading suspected diagnosis. Soft tissue swelling and edema are best detected with fat-suppressed images, where the resolution is much greater with MRI than with plain radiographs or the CT scan. Bony cortical changes, periosteal reaction, soft tissue edema, abscesses, and sinus tracts are clearly shown on MRI.

It is likely that in the next decade MRI will supplant bone scans as the preferred imaging modality for evaluating osteomyelitis. When done with STIR images, MRI has a 100% negative predictive value and osteomyelitis can be essentially excluded in the presence of a normal MRI.\(^{25}\) The sensitivity of MRI is reported to be between 88 and 100%, with a specificity of 75 to 100%.\(^{26}\) MRI with gadolinium contrast also has a higher sensitivity and specificity than radionuclide bone scans in the diagnosis of vertebral osteomyelitis\(^{25-27}\) (Fig. 134-7). The differential diagnosis for the MRI findings in acute osteomyelitis are trauma, noninfectious inflammatory and metabolic lesions, histiocytosis, tumors, and cancer. In cases where a surgical procedure will be done to obtain a microbiologic diagnosis or is needed to treat osteomyelitis, MRI has obvious advantages over a radionuclide bone scan in detailing the anatomy for the surgeon. One drawback to MRI is the presence of metal in bone, especially prosthetic joints. Metal may cause distortion of the signal in the area adjacent to a joint prosthesis, but this does not exclude MRI scan in this group of patients.\(^{27,28,29}\)

**Microbiologic Diagnosis.** The most direct and often most effective way to diagnose osteomyelitis is to obtain infected bone by needle aspiration or surgical resection. Culture results from infected bone allow for specific antimicrobial therapy. Cultures of draining fistulas or sinus tracts are not an acceptable substitute because the organisms cultured from these sites are often different from those in the underlying infected bone.\(^{3,34}\) Because osteomyelitis may be polymicrobial or due to unusual microorganisms, especially in immunocompromised patients, cultures for fungal and anaerobic organisms should be obtained.

Particularly in cases of hematogenous osteomyelitis, cultures of blood, urine, cerebrospinal fluid, and pus from other sites of infection can help uncover the infecting bacteria. Blood cultures in patients with acute untreated osteomyelitis are positive for the offending bacteria approximately 50% of the time.\(^{46}\) In children with hematogenous osteomyelitis, it is not unusual to identify the infecting organism in other bodily fluid cultures in addition to blood cultures. Blood cultures are almost always negative in patients with chronic forms of osteomyelitis.\(^{34}\)

The likelihood of establishing a bacteriologic diagnosis in acute osteomyelitis is 80 to 90%, but in some cases, even culturing of resected bone yields no organism. Possible reasons for this are poor culture techniques and inadequate preparation of recovered tissue for culture, previous antibiotic
treatment, and culturing from necrotic ischemic regions that may be devoid of bacteria.34,51

When the emergency physician is confronted with a patient with possible osteomyelitis, the diagnostic options can seem confusing. The algorithm in Fig. 134-8 provides a simplified approach to the management of the patient with suspected osteomyelitis. A few key points should be considered when using this algorithm:

1. Radiographs lag behind the clinical picture.
2. When there is little clinical support for a diagnosis of osteomyelitis and the initial bone scan or MRI is negative, it is extremely unlikely that the patient has osteomyelitis.
3. In infants and children the amount of radiation exposure with imaging techniques must be considered.64
4. In easily accessible bones, aspiration is a low-risk procedure that will often help to establish a microbiologic diagnosis.
5. If the clinical presentation strongly suggests osteomyelitis, a lengthy diagnostic workup should not delay empirical treatment. Cultures of blood, urine, and other appropriate sites should be obtained and antibiotic treatment started.
6. The cost of imaging tests for osteomyelitis must be considered in deciding how to pursue the diagnosis. Expense must be weighed against the benefit of early diagnosis of osteomyelitis, the prevention of chronic osteomyelitis, and the numerous surgeries and increased length of treatment associated with this diagnosis.

Clinical Subsets of Osteomyelitis

Acute hematogenous osteomyelitis (AHO) is the most common form of osteomyelitis, but it has different presentations, diagnosis, and treatment in adults compared with children. The other main type of osteomyelitis, arising from a contiguous focus of infection, has special diagnostic and management features. This section reviews the common clinical subsets of osteomyelitis.
Osteomyelitis in Children

Osteomyelitis in children tends to be acute, almost always arises from hematogenous seeding of bone, and can often be treated with antibiotics alone. AHO is seen in children as young as 3 months and as old as 16 years. Bacteremia is the presumed cause of bone infection. *S. aureus* is the most common infecting organism in children of all ages except neonates (see Table 134-1). As noted above, *H. influenzae* is no longer a common cause of AHO.

AHO has a well-established male preponderance (male/female ratio of 2 to 3:1) and involves long bones approximately 80% of the time. The site of infection is usually the distal metaphysis, but up to 30% of AHO occurs in other parts of the bone. The epiphysis may be involved in a “subacute” type of osteomyelitis. Children with AHO may have fever, chills, vomiting, dehydration, and malaise; but they usually do not appear toxic. Most children have characteristic pain, limited use, and point tenderness in the involved limb. The diagnostic evaluation for AHO is listed in Fig. 134-8. Blood cultures are positive for the bacterial cause of osteomyelitis in 60% of patients with AHO. A positive blood culture and a physical examination consistent with osteomyelitis may be sufficient to make a diagnosis of AHO. Figures 134-2 and 134-5 show a typical radiograph and bone scan of AHO, respectively.  

Neonatal osteomyelitis is increasingly reported and may be difficult to diagnose because of minimal systemic findings. Neonatal osteomyelitis is more commonly seen after abnormal pregnancies or deliveries and often accompanies other acute illnesses. Multiple sites of bony involvement are found in approximately half the reported cases. Because of the special vascular anatomy of the neonate, septic arthritis often accompanies osteomyelitis. Osteomyelitis in the neonate is more common in flat bones, such as the facial bones. Group B streptococci are becoming the leading causative bacterium in neonatal osteomyelitis, but staphylococcal species are still common. Skeletal scintigraphy is of limited value in diagnosing neonatal osteomyelitis. The reasons are an inadequate inflammatory response in the neonate, the small size of bones and joints, and the ability of the epiphyses to concentrate the radiolabeled isotope, making it difficult to distinguish between infection and normal activity in this area. Plain radiographs show abnormalities within days of development of neonatal osteomyelitis and are usually positive by the time the disease is suspected.

Two less common forms of osteomyelitis can occur in children: subacute osteomyelitis and chronic recurrent multifocal osteomyelitis (CRMO). Subacute osteomyelitis refers to a form of the disease in which clinical symptoms and signs are slow to appear and radiographs show small areas of osteomyelitis, usually in the metaphysis of long bones. Cultures of blood and bone are negative more than 50% of the time and, when positive, usually implicate staphylococcal species. Like subacute osteomyelitis, CRMO usually affects older children (6–10 years) and adolescents. CRMO is characterized by small foci of infection at various sites in the skeleton. The disease is defined by multiple episodes of indolent infection. Diagnosis is made by radiographs; culture of the bony sites is almost always negative. This disease may be associated with a type of psoriasis.

Another form of subacute osteomyelitis is Brodie’s abscess. This is a localized form of subacute osteomyelitis that also
Vertebral Osteomyelitis

Vertebral osteomyelitis usually afflicts older adults in a manner analogous to AHO in children and appears to be increasing in frequency as the population ages. The spine is susceptible to bacterial infection because the venous system surrounding vertebral bodies is valveless (permitting two-way flow of blood) and has transverse and longitudinal anastomoses. Bacteria that reach the spine and enter the venous plexus are more likely to aggregate and cause infection in this slow-moving system. Infection can readily spread to adjacent vertebral bodies. A clear source of bacterial hematogenous seeding with positive blood cultures occurs in approximately 40% of cases of vertebral osteomyelitis. *S. aureus* (including MRSA) is the most common offending agent in vertebral osteomyelitis, followed by aerobic gram-negative rods from urinary or gastrointestinal sources.

Only 10% of patients with vertebral osteomyelitis appear septic or toxic; the rest have a subacute presentation. In most patients, physical examination will reveal back pain and tenderness over the spinous process. Neurologic deficits are reported in less than 20% of patients with vertebral osteomyelitis and are often an indication of an epidural abscess. Up to 50% of patients with these abscesses present without fever or leukocytosis. On laboratory testing, the ESR is commonly elevated greater than 50\(\text{mm/hr}\) and the CBC may demonstrate anemia of chronic disease. Up to 30 to 60% of the time. The disease resolves with nonoperative treatment.72,75 The diagnostic procedure of choice for vertebral osteomyelitis is needle biopsy which can provide multiple specimens for microbiologic and pathologic examination. In order to avert the potentially catastrophic progression to spinal cord compression, ED patients who present with a clinical picture consistent with vertebral osteomyelitis should have the diagnosis rapidly confirmed either through imaging or by direct needle biopsy performed by a surgeon, with or without CT guidance. Patients who are at increased risk for paralysis include elders, those with cervical spine osteomyelitis, and those with serious underlying diseases, such as rheumatoid arthritis or diabetes mellitus.

Most patients with vertebral osteomyelitis require prolonged antibiotic therapy. Surgical therapy may also be necessary, especially when there is spinal cord compression, abscess formation, persistent pain, progressive deformity, and recurrence after adequate treatment.76 A variant of vertebral osteomyelitis seen in children that must be distinguished is diskitis. This subacute disease is thought to be a low-grade infection (usually *Staphylococcus* species) within the disk, sometimes extending to the adjacent vertebral plates. The child complains of back pain and may refuse to walk. Bone scintigraphy may show increased uptake in the disk space. Single-photon emission computed tomography imaging and pinhole collimation can accurately identify the site and extent of involvement. As in adults, MRI will demonstrate the anatomy of diskitis better than bone scintigraphy. CT is used to guide aspiration. Cultures of the disk from needle aspiration are reported to be positive for bacteria 30 to 60% of the time. The disease resolves with nonoperative treatment.72,75

Post-traumatic Osteomyelitis

Post-traumatic osteomyelitis is a form of contiguous-focus osteomyelitis that results from open fractures, surgery and invasive procedures, burns, bites, and puncture wounds.

At least 10% of open fractures later develop osteomyelitis, and the tibia is the most commonly affected bone. The fracture site may be directly contaminated from the environment or iatrogenically contaminated from emergency procedures or surgery. The intraoperative implantation of prosthetic devices further increases the chance of infection. Extreme damage to adjacent soft tissues may result in a necrotic nidus of infection that can spread to bone. Polymicrobial infection is more common with this type of osteomyelitis. The imaging of post-traumatic osteomyelitis is complicated by changes induced by surgery and new bone formation in the fracture. Imaging modalities that are best in this situation are MRI, CT, and 18F-FDG PET.77,78

Infection that is due to direct inoculation associated with joint arthroplasty may become evident within 12 weeks after the surgery. These patients generally do not report relief of their pain after the surgery. Patients who develop symptoms of infection more than 12 weeks after surgery and who have postoperative improvement of their pain are considered to have a hematogenous source of their infection. If either of these presentations are recognized within the first 2 weeks of
onset of infectious symptoms, the prosthesis is considered salvageable. After 2 weeks, the chances of eradicating the infection without removing the prosthesis decreases substantially. 79–83

Postoperative osteomyelitis is difficult to diagnose. Fever is often absent and the patient often presents with a painful, unstable joint on physical examination. *S. aureus* and *S. epidermidis* account for 75% of postoperative and prosthesis-related osteomyelitis. Radiographs are often negative but may show subtle signs of bone resorption about the prosthetic components. It is difficult to distinguish mechanical from infectious loosening, so joint aspiration and synovial fluid analysis is necessary. However, this should only be attempted in the sterile operating room to avoid introducing infection. Other imaging techniques such as CT, MRI, and 18F-FDG PET are used but are also difficult to interpret due to scatter from the metallic components and postoperative changes. The most common form of postoperative osteomyelitis is infection of a hip prosthesis, which occurs in 1 to 5% of hip replacement surgeries. It has been shown experimentally that bacteria can become immersed in an extremely adherent material called the gycocalyx, which binds to the inert substance of the prosthesis. Systemic antibiotics cannot penetrate this gycocalyx, and surgical removal of the prosthesis is usually the only way to cure the infection.84 Puncture wounds to the feet have approximately a 2% incidence of developing osteomyelitis. The causative organism is usually *P. aeruginosa* or *S. aureus*. Other puncture wounds are nosocomial—in the form of subclavian venipuncture, fetal scalp monitors, and other invasive procedures. Osteomyelitis can result from inoculation of bone with bacteria during these punctures.

**Diabetic Foot Osteomyelitis**

The pathologic changes induced by long-standing diabetes mellitus encourage the development of osteomyelitis. Foot infections are common in diabetics because of compromised vascularity. Peripheral neuropathy is present in a majority of diabetic patients, and this leads to repetitive trauma and loss of the protective barrier of the skin and foot ulcers. Once the skin has been violated and infected, the altered host defense of diabetic patients allows infection to occur and spread. The small bones and phalanges are most often affected. Infection spreads first to the periostium and then to the cortex and may finally disrupt medullary bone. The initial phase of foot infection in diabetic patients may exacerbate preexisting hyperglycemia. This allows bacteria to replicate at an increased rate and impairs leukocyte function, with defective chemotaxis, abnormal phagocytosis, and decreased bacterialid function.83 Defective antibody synthesis and decreased complement levels also exacerbate osteomyelitis in diabetics. The typical patient with diabetic foot osteomyelitis is more than 50 years old and has advanced insulin-dependent diabetes. More than 60% of such patients have polyneuropathy, more than 50% have retinopathy, and at least 30% have concurrent cardiovascular disease.86,87

Local findings in diabetic foot infections consist of swelling, erythema, and sometimes pain. Indolent ulcers and frank cellulitis are seen in more than 50% of cases. Because the process is often chronic, radiographic changes may have sufficient time to develop. Mottled lytic lesions are typical, and air may be present in the soft tissues. The bone scan is of limited value because of generalized poor perfusion in the area and the frequency of concurrent soft tissue infection. The only reliable way to make the bacteriologic diagnosis is by surgical culture of the bone; however, if a wound can be probed all the way to the bone, wound cultures have an 89% positive predictive value for osteomyelitis.87,88 Bone biopsy for diabetic foot osteomyelitis has a reported sensitivity of 94%.90 Diabetic foot osteomyelitis is usually polymicrobial. The most common organism is *S. aureus*. Other common organisms include streptococci, Enterobacteriaceae, and anaerobes. Surgical treatment is often required, and severe cases commonly lead to amputation of toes or portions of the foot. However, treatment with intravenous (IV) followed by oral antibiotics can be successful in some patients. In general, patients are treated with a longer treatment course of about 8 to 10 weeks.90

**Osteomyelitis in Sickle Cell Disease**

Patients with sickle cell disease are at increased risk for hematogenous infection, including osteomyelitis. Macrophage function is impaired in sickle cell patients, rendering them susceptible to infections with encapsulated organisms. AHO in children with sickle cell disease has two major differences from AHO in other children. First, infection in sickle cell disease is usually located in the diaphysis of long bones as opposed to the metaphysis as is seen in other AHO patients. Second, although *S. aureus* is still the most common bacterium in children with sickle cell disease who develop osteomyelitis, *Salmonella* species are the next most common infecting organism. The reason patients with sickle cell disease are predisposed to bone infection with *Salmonella* is not completely understood, although it is postulated that microinfarcts in the bowel allow *Salmonella* bacteremia to seed the bloodstream and become hematogenous osteomyelitis.91

The differentiation of bone infection from bone infarction in sickle cell patients is a challenge. Fever, a toxic appearance, and an elevated ESR are all more commonly associated with osteomyelitis than with bone infarction. Plain radiographs are not helpful in distinguishing between the two entities. Skeletal scintigraphy may help make the diagnosis. The best method appears to be 99mTc MDP followed by gallium or indium scanning. Although both infection and infarction may show increased uptake on the technetium scan, the gallium or indium scan should be “hot” with osteomyelitis but “cold” with sickle cell infarction. Another approach is to note the response to conservative therapy: Bone infarctions usually improve within 24 to 48 hours, whereas bone infection worsens.53,92,93 Antibiotic treatment of osteomyelitis in the sickle cell patient should include coverage against *Salmonella*, for example, with a third-generation cephalosporin.

**Chronic Osteomyelitis**

Historically, chronic osteomyelitis usually resulted from inappropriate or inadequate treatment of AHO. However, most chronic bone infections now occur as a complication of posttraumatic infection, surgical procedures, or diabetic foot infections. The inflammatory response to infection triggers bone resorption, cartilage destruction, and ultimately leads to bone death. The necrotic bone acts like a foreign material, providing an inanimate surface to which microorganisms adhere.94 Clinical signs that the infection has become chronic include the formation of sequestra and the presence of draining tracts or fistulas (Fig. 134–9). This infection is almost always polymicrobial and commonly involves anaerobes. Bone scans are of limited use in chronic osteomyelitis, as it is difficult to differentiate active foci of infection and identify improvement of infection. Cultures of sinus tracts are not a reliable method for predicting which bacteria are active in the underlying bone infection. Therefore, direct biopsy of bone is the only option for accurately diagnosing most cases of chronic osteomyelitis.20,86,95 Chronically established orthopedic infection can be
may occur through sites of osteomyelitis. Deformed extremity on the affected side. Pathologic fractures permanent growth alteration can occur, resulting in a shorter or
an invasive, suppurative process can lead to septic arthritis, Depending on the location of osteomyelitis, local extension of infection, early antibiotic therapy is less crucial unless the presentation suggests bacteremia or necrotizing soft tissue infection. The ideal antibiotic for treating osteomyelitis should be bactericidal against the offending bacteria, have low toxicity, be chemically stable at the site of infection, and be relatively inexpensive. The low pH of infected bone may limit the bactericidal action of some antibiotics, particularly the aminoglycosides. Cephalosporins and penicillins are more stable in this environment. The emergency physician will usually have to empirically initiate broad-spectrum treatment of suspected osteomyelitis and should be aware of regional resistant patterns.

The antibiotic of choice for osteomyelitis should be active against beta-hemolytic streptococci and staphylococci, including MRSA. Although gram-negative organisms are uncommon pathogens, the serious consequences of inadequate treatment justify the inclusion of anti-gram-negative coverage in the initial drug regimen. Once culture results are obtained, the antibiotic regimen can be tailored.

ED care of most types of osteomyelitis involves treatment of an infection that has been present for days or weeks. In the case of post-traumatic osteomyelitis, emergency care may help to prevent the disease. The proper management of open fractures in the field is to cut away surrounding clothing, pour sterile saline or water over the exposed bone, and cover the wound with moist sterile gauze bandages or a sterile sheet. Only in the case of severe vascular compromise to the distal limb should an open fracture site be manipulated or realigned because of the danger of further contaminating the wound. Since wound surface cultures in the emergency setting are not reliable in predicting future pathogens in bone infections, they need not be done as part of emergency care.

Treatment of osteomyelitis often requires a combined medical and surgical approach. This is usually true when osteomyelitis is caused by direct inoculation into bone or spreads from a contiguous focus of infection. If the area of osteomyelitis is small, aspiration or resection of the bone abscess may be both a diagnostic and therapeutic procedure. Since wound surface cultures in the emergency setting are not reliable in predicting future pathogens in bone infections, they need not be done as part of emergency care.

AHO in children can be treated with antibiotics alone. In other situations, such as diabetic foot osteomyelitis and chronic osteomyelitis, the use of antibiotics with surgical débridement is necessary to eradicate the infection.
The first priority remains adequately treating *Staphylococcus* species with a penicillinase-resistant penicillin such as oxacillin or nafcillin or a first-generation cephalosporin. In patients with a severe penicillin allergy, clindamycin is an acceptable alternative. MRSA is usually sensitive to clindamycin, linezolid, or combination therapy of vancomycin with rifampin. Nonenterococcal streptococci are usually sensitive to antibiotics used to combat staphylococci. Gram-negative bacteria, including Enterobacteriaceae, *Escherichia coli*, *Proteus mirabilis*, and *Serratia marcescens*, are rare causes of osteomyelitis. Nonenterococcal streptococci, aminoglycosides, imipenemcilastatin, and ampicillin are the usual choices for broad gram-negative coverage. Beyond this initial broad-spectrum therapy, prophylactic treatment for anaerobic bacteria, *Pseudomonas*, and fungal organisms must be based on clinical suspicion. Due to emerging resistance patterns, fungal bone and joint infections are best treated with the azole antibiotics such as fluconazole and itraconazole.

The incidence of antibiotic resistance is increasing. Resistance to both penicillinase-resistant penicillins (oxacillin and methicillin) and fluoroquinolones by staphylococci, vancomycin by enterococci, and imipenem by pseudomonads have all been reported. Therefore, if the bacterium is identified in the emergency setting, it is important to select the most specific antimicrobial agent based on regional resistant patterns.97,99,107 The increase in antimicrobial resistance highlights the need for new antibiotics to expand therapeutic options. Second-generation fluoroquinolones, such as ciprofloxacin and lomefloxacin, and third-generation agents, such as levofloxacin, offer excellent bone and joint penetration and are active against a broad spectrum of gram-positive and gram-negative organisms. Since blood concentrations are similar between oral and parenteral administration of these drugs, development of oral treatment protocols for osteomyelitis is being studied.2,97,99,107 Successful treatment of osteomyelitis correlates best with serum levels of antibiotics, not the route of administration. The standard recommendation is that the antibiotic used should achieve serum levels eight times greater than its minimum inhibitory concentration. If the serum concentration of an antibiotic is bactericidal, bactericidal levels in bone will almost always be present.107 Table 134-1 lists common treatment regimens for the variety of bacteria that cause osteomyelitis. The standard recommendation is parenteral antibiotics for 4 to 6 weeks and then an oral course of antibiotics.

Treatment of chronic osteomyelitis is a difficult surgical problem. Instillation of antibiotic-containing beads into infected bone can help eradicate the infection so that bone grafts can be successfully used in chronic osteomyelitis.108 Hyperbaric oxygen therapy is reported to be effective in treating chronic osteomyelitis in noncontrolled clinical case series, and may work best in diabetic foot osteomyelitis. Further randomized clinical trials are necessary to confirm the favorable results seen in case series.110

**Disposition of the Patient with Osteomyelitis**

Patients with osteomyelitis are admitted for IV antibiotic treatment. A subset of these patients will also need operative débridement. Oral antibiotics that have the same bioavailability as their IV forms can be used; however, an initial IV course of antibiotics is still recommended. Some recent studies have demonstrated good results with outpatient treatment of osteomyelitis. After steady-state serum antibiotic levels have been achieved, patients can be treated with outpatient IV antibiotic therapy.111,112

---

**CLINICAL FEATURES OF SEPTIC ARTHRITIS**

**Diagnosis of Septic Arthritis**

It is estimated that 20,000 cases of septic arthritis are diagnosed per year. Septic arthritis most commonly results from hematogenous migration of bacteria into a joint. Like osteomyelitis, septic arthritis may also result from spread from a contiguous focus of infection or by direct inoculation of bacteria. Direct inoculation can result from penetrating trauma or iatrogenically, as a consequence of any procedure that invades the synovium, such as joint aspiration or injection. Septic arthritis may occur concomitantly with osteomyelitis, with infection spreading from bone to joint, and osteomyelitis may also be the result of septic arthritis. Septic arthritis occurs in all age groups but is most common in children. It is almost always a monoarticular process; polyarticular involvement is present in fewer than 10% of pediatric cases and fewer than 20% of adult cases.8,14,26,113

Septic arthritis is most likely to occur in the joints of a lower extremity. In infants and children, the knee and hip are most often infected. In adults the knee is the site of septic arthritis 50% of the time, followed by the hip (20%), shoulder (8%), ankle (7%), and wrist (7%). As noted previously, since the synovial membrane extends beyond the epiphysis and attaches to the metaphysis in the knee, hip, and shoulder joints, infection can easily spread from the metaphysis of the femur or humerus into the joint.14,16,114-116

**History and Physical Examination**

The onset of septic arthritis is usually more acute than osteomyelitis. The predominant symptom of septic arthritis is joint pain, exacerbated with range of motion. Many children who have septic arthritis will not use the involved limb at all. If the hip is infected, the child may present with referred pain to the thigh or knee. Immune-suppressed patients, especially those on corticosteroids, may develop septic arthritis with minimal joint pain. It is important to ascertain the presence of underlying joint disease such as osteoarthritis, gout, rheumatoid arthritis, joint surgery, and the presence of other conditions, such as IV drug use, that predispose patients to septic arthritis. In these patients, a careful history may help differentiate chronic joint pain from the acute pain associated with septic arthritis. Greater than 80% of children and 40% of adults have a fever on presentation; however, constitutional symptoms such as weakness, malaise, anorexia, nausea, and diffuse myalgias are inconsistently reported.8,13,16,116

Tachycardia and hypotension may indicate a generalized septic process. Examination of the skin, nose, ears, and pharynx may reveal a focus of infection. In the neonate or infant, there may be “pseudoparalysis” of the affected limb. This can be mistaken for a neurologic problem; however, an isolated true paralysis is far less common than septic arthritis. The inability of a child to bear weight on a lower extremity or to spontaneously move any joint must be considered a sign of septic arthritis until proven otherwise.

In the older child and adult, signs may be more localized. The extremity will usually be held motionless in the position of greatest comfort, which is slight flexion. Palpation of the septic joint causes exquisite pain, and any maneuver that stretches the synovium, such as flexion and extension, will cause severe pain. The cardinal signs of inflammation, swelling, erythema, and warmth, are commonly found in the affected joint. The hip joint, with its deeper location, may not produce obvious external findings when infected; however, passive range of motion will be painful. Periarticular processes such as
bursitis, tendinitis, and cellulitis may produce erythema, warmth, and tenderness, but these processes can be differentiated from septic arthritis since palpation of the joint line and maneuvers that stress the synovium and joint are not usually painful. Periarticular processes also do not commonly produce an effusion. In general, the triad of fever (seen in 45–60% of cases), pain (seen in 75% of cases), and impaired range of motion suggests septic arthritis. One caveat with the physical examination is that an increasing number of adult patients are on chronic immunosuppressive drugs, and in these patients the classic history and examination findings may be significantly less dramatic than in their immunocompetent counterparts.\(^{14,15,116}\)

**Diagnostic Strategies of Septic Arthritis**

**Joint Aspiration and Joint Fluid Analysis.** The diagnosis of septic arthritis requires joint fluid for culture and analysis. It is fortunate that the knee joint is both the most likely to be infected and the easiest to aspirate. Other joints such as the hip are more difficult to aspirate and may require orthopedic surgical consultation. Ultrasound and fluoroscopy-guided aspiration are adjunct modalities used to obtain fluid from the joint and may be useful in detecting early, less obvious intra-articular fluid collections.\(^{114}\) However, the absence of sonographic fluid does not rule out septic arthritis as the cause for joint pain. When attempting to obtain synovial fluid from the hip under fluoroscopy, a small amount of contrast material should be injected into the joint during aspiration to confirm that the needle has entered the intra-articular space.\(^{115,117}\) Sterile technique should always be practiced; however, the risk of introducing infection into a joint during intra-articular aspiration or injection has been reported to be only 0.4% or approximately 1 in 10,000 joint injections or aspirations.\(^{15,26}\)

Because joint fluid analysis is not done as often as other diagnostic tests in the ED, a joint fluid protocol form is useful to ensure that all necessary tests are prepared and ordered properly. Joint fluid cultures must be inoculated as soon as possible after the fluid is obtained. The laboratory should include special media to test for fastidious organisms such as *Neisseria gonorrhoeae* and *H. influenzae*.\(^{4,26}\) Anaerobic and fungal organisms should also be cultured.

One method that may increase the yield in isolating bacteria from joint fluid is to inoculate blood culture bottles with joint fluid immediately after joint aspiration. This allows some bacteria, which would normally die before being inoculated on culture media in the laboratory, to survive and grow in the blood culture bottle (brain-heart infusion broth).\(^{4,16}\) Joint fluid culture results in clinically suspected septic arthritis are negative in 20 to 25% of cases. This may be due to an inadequate joint fluid sample, poor culturing techniques, the presence of fastidious organisms, or misdiagnosis of the joint inflammation. In addition, leukocytes may have cleared bacteria from the joint space; however, the bacteria may still persist in the synovial membrane and may be detected by a synovial biopsy.\(^{4,16,26}\)

The definitive test to determine bacterial arthritis is joint fluid culture. Other tests of the synovial fluid are commonly obtained, but the efficacy of these additional tests is debated. The Gram’s stain, WBC count and differential, and the ratio of the joint fluid glucose to serum glucose have traditionally been used to differentiate bacterial arthritis from other joint diseases and can be included as adjunct studies in the evaluation of the patient with joint pain. The primary reason for the decreasing utility of the traditional joint fluid tests is the number of patients who have a chronically activated or suppressed immune response in the infected joint. The synovial fluid leukocyte count in a septic joint is often greater than 50,000 cells/mm\(^3\) with a predominance of polymorphonuclear leukocytes, but other processes can give similar cell counts, and up to 30% of patients with septic arthritis have been documented to have counts less than 50,000 cells/mm\(^3\).\(^{3}\) The fasting joint fluid glucose level is often lowered in patients with septic arthritis, and the joint fluid/serum glucose ratio is less than 1:2; but this test is also not reliable. The joint fluid lactate level is often higher in infected joints than in inflamed joints, but this test does not appear to be more helpful than the glucose ratio, particularly in partially treated septic arthritis. Joint fluid WBC counts and glucose may be most helpful to rule out septic arthritis when the WBC count is low (<10,000 cells/mm\(^3\)) and the glucose is normal.\(^{4,8,26,116}\) The examination under polarizing microscopy for the presence of crystals may be of some use in differentiating inflammatory from noninflammatory joint disease but is not helpful in separating infectious from noninfectious inflammatory joint disease.

When only a drop or two of synovial fluid can be recovered from a joint aspiration, the emergency physician must establish priorities for diagnostic tests. The single most important test is a bacterial culture. Culture of the synovial fluid or of synovial tissue itself (obtained by arthrotomy) is the only definitive method of diagnosing infective arthritis. If extra fluid is available after obtaining a culture, it can be used to obtain a Gram’s stain and smear, and then a cell count and crystal analysis.\(^{4,14,16}\) Since therapeutic decisions should not be delayed until results of the culture are available, the Gram’s stain is used to guide antibiotic treatment; however, empirical treatment should not be delayed if the Gram’s stain is negative. The Gram’s stain is less than 60% sensitive for detection of bacteria in synovial fluid.

Blood tests are not consistently helpful in making a diagnosis of septic arthritis. Two sets of blood cultures should be obtained; however, it should be noted that blood cultures reveal the infecting organism in only 25 to 50% of cases. The ESR is elevated in approximately 90% of cases of septic arthritis and, along with the CRP, is used to track resolution of the infection. A WBC count greater than 10,000 cells/mm\(^3\) may suggest a systemic illness, but is present in only 50% of patients with septic arthritis, and many sterile inflammatory processes create a similar leukocytosis. Cultures of infectious foci, such as the throat, cervix, and urine, may demonstrate the bacteria responsible for septic arthritis.\(^{4,14,16,116}\)

Plain radiography is not an effective tool for the early evaluation of septic arthritis but may detect surrounding osteomyelitis. Radiographs may reveal a joint effusion that displaces capsular fat planes. Clinically, this is most helpful in the hip joint, where it is difficult to detect an effusion on physical examination. In most joints the small areas of attachment of the synovial membrane to bone are devoid of cartilage. These “bare areas” at the margins of the joint appear as lucencies or erosions early in the course of septic arthritis. Bone beneath the articular cartilage may start to erode 1 to 3 weeks into the disease. Air density in the joint may be a sign of infection with gas-forming organisms or may be the result of a previous joint aspiration.\(^{3,5,2}\) In patients with existing joint disease, radiographs provide minimal assistance in diagnosing septic arthritis.

Skeletal scintigraphy has been used in the diagnosis of septic arthritis. Its main advantage is in detecting septic arthritis earlier than other imaging techniques. In septic arthritis, scintigraphy shows symmetrical areas of increased uptake on both sides of the joint. In a three-phase \(^{99m}\)Tc scan, all three phases will be “hot” with septic arthritis; however, it may be difficult to distinguish osteomyelitis in the metaphysis of a long bone from septic arthritis in the adjacent joint. In general,
Complications of Septic Arthritis

Septic arthritis leads to two types of serious complications, those involving the joint itself and those that are systemic. Children are at great risk for epiphyseal damage if the infection extends through subchondral bone. This can result in impaired growth and limb length discrepancy. Other tissues adjacent to the joint can be invaded. Bursae, tendons, ligaments, and muscles can be destroyed by the suppurative process. Sinus tracts may lead the infection out through the skin. In the hip, the pressure and edema of a septic synovial effusion can occlude blood supply, resulting in avascular necrosis of the femoral head. Septic hip arthritis in both children and adults needs to be promptly diagnosed and treated with drainage to prevent destruction of the hip joint. In other joints the sequela of uncontrolled septic arthritis is ankylosis. The joint becomes stiff, fused, and devoid of articular cartilage. Septic arthritis can result in systemic sepsis, especially in elderly and immunocompromised patients.

Clinical Subsets of Septic Arthritis

Septic Arthritis in Infants and Children

Septic arthritis is more common in children than in adults, and the incidence of septic arthritis is twice that of osteomyelitis in children. Of pediatric cases, two thirds occur in children less than 2 years old, and boys are affected twice as often as girls. The bacterial etiologic agent of septic arthritis varies with age. Overall, S. aureus is the most common infecting organism in all pediatric age groups, followed by group A streptococci and Streptococcus pneumoniae. In neonates, group B streptococci, S. aureus, and gram-negative enteric bacilli are usual pathogens. Candida albicans must also be considered in neonates and premature infants. Since the widespread introduction of the H. influenzae type B vaccine, S. aureus has become the most common cause of septic arthritis in children 3 months to 5 years of age. In this age range, concomitant respiratory infection or otitis media is often present. Prior trauma or skin infection may be more common with staphylococcal septic arthritis. Even with full culturing of joint fluid and blood, a causative organism is not discovered in up to 30% of cases of septic arthritis in children, and prior antibiotic treatment in children decreases the yield on synovial fluid cultures from 80 to 38%. If the hip joint is infected, the complication rate is higher, and permanent joint damage is more likely. This is especially true in infants, particularly those who have coexisting septic arthritis and osteomyelitis.

Gonococcal Septic Arthritis

N. gonorrhoeae is the most common cause of septic arthritis in teenagers and young adults. In the United States it is most common in those with lower socioeconomic status in urban areas. A person with gonorrhea of the urethra, cervix, rectum, or pharynx has a 1 to 3% chance of developing disseminated gonococcal infection (DGI). Even though gonorrhea is more common in men, women are more commonly afflicted with DGI. In fact, more than 75% of the cases of DGI occur in women, especially during pregnancy or after menstruation when the alkaline vaginal environment makes the organisms more resistant to host defenses in the bloodstream and therefore more likely to disseminate.

The strains of N. gonorrhoeae that cause disseminated infection and septic arthritis have different characteristics than those that cause local infection. Those strains that cause disseminated infection contain outer membrane proteins, which make them resistant to serum bactericidal activity. These strains are not more resistant to antibiotics than other types of N. gonorrhoeae; however, penicillin-resistant and fluoroquinolone-resistant gonococcal infections appear to be increasing in some parts of the world, including the United States. The common finding of sterile joint fluid in DGI, even when mucosal cultures are positive, suggests that the host immune response plays a significant role in the development of purulent arthritis.

Most, but not all, patients with DGI are symptomatic with a local genital or oral infection. Symptoms may be less noticeable in women, and this is likely the reason for delays in treatment and a higher incidence of the disease. The time for local infection to disseminate can vary from 1 day to several weeks. Symptoms begin soon after gonococcal bacteria enter the bloodstream. On presentation, fever and chills are often present. The classic triad of gonococcal bacteremia is migra-

Figure 134-10. Ultrasound of the right hip in an 8-year-old girl with septic arthritis. A significant joint effusion can be seen just superior to the round contour of the femoral head. Joint aspiration revealed purulent fluid with a WBC count of 71,000 cells/mm³.
tory polyarthritis, tenosynovitis, and dermatitis. Asymmetrical polyarthritis, which may be migratory, is the most common presenting complaint, occurring in two thirds of cases, with 25% of patients having monoarthritis. The arthralgia is usually asymmetrical and most frequently involves the knee, elbow, wrist, metacarpophalangeal, and ankle joints. The sacroiliac and sternoclavicular joints may be involved, although these sites are far less common. Tenosynovitis occurs in two thirds of patients with bacteremia, usually occurring in the hands and fingers. Dermatitis also occurs in two thirds of patients and presents in a variety of forms. Most commonly, there are scattered painless, nonpruritic, small (0.5- to 0.75-cm) papules distributed below the neck that can involve the palms and the soles. These papules can turn into pustules on a broad erythematous base with either a necrotic or hemorrhagic center. Usually, there are fewer than 50 lesions, distinguishing DGI from the rash of meningococcus.

Septic arthritis develops in approximately 40% of patients with DGI. This is usually a monoarticular process, although polyarticular arthritis has been reported. The patient will present with classic signs of a septic joint, including a joint effusion, warmth, tenderness, decreased range of motion, and marked erythema. There is usually no clear progression of the disease from polyarthralgias to purulent monarthritic arthritis and many patients are afflicted with dermatitis and tenosynovitis without developing true arthritis. Some of the strains of *N. gonorrhoeae* that produce disseminated gonococcal infection favor the development of tenosynovitis and dermatitis, whereas others favor the development of purulent arthritis.

The diagnosis of gonococcal arthritis is made by synovial fluid culture results. Joint fluid analysis in gonococcal arthritis reveals some differences in comparison with other types of bacterial arthritis. The synovial fluid WBC count in gonococcal arthritis is often less than 50,000 cells/mm³. Gram’s stains of aspirated joint fluid are positive for bacteria only 25% of the time in gonococcal arthritis, and cultures of the joint fluid are negative in approximately 50% of cases. This may be due to poor culturing techniques, or because a suppurative reactive process can occur in the joint in DGI even when bacteria are no longer present. When gonococcal arthritis is suspected, cultures of the synovial fluid have to be done on prewarmed chocolate agar for the highest yield. Also, it is important to culture the mucosal surfaces for *N. gonorrhoeae* when clinical suspicion for gonococcal arthritis is high because these may be the only places where bacteria are readily recovered. In 80% of cases, cultures of the genital tract, pharynx, or rectum will be positive. Gonococcal septic arthritis responds rapidly to antibiotic treatment and, unlike other types of bacterial arthritis, rarely causes permanent damage to the joint.

Patients with septic arthritis will require hospital admission with antibiotic coverage against the likely pathogens until laboratory results are available. With the rise in fluoroquinolone-resistant gonorrhea, the recommended treatment of gonococcal arthritis is a third-generation cephalosporin, such as ceftriaxone, cefotizoxime, or cefotaxime. Patients should be given the first dose intravenously or intramuscularly in the ED and admitted until culture results are available. In some cases, patients with reliable follow-up can be sent home with an oral regimen that should be continued for 1 week.

### Lyme Arthritis

Lyme disease is caused by infection with a spirochete, *Borrelia burgdorferi*, that is transmitted by the *Ixodes* tick and is an important cause of arthritis in endemic areas, including states between Maryland and Maine, Wisconsin, Minnesota, California, and Oregon. The spirochete induces an immune response that leads to a reactive arthritis. While a history of a tick bite is important to ascertain, up to 30% of people do not remember being bitten. Patients with Lyme arthritis present with migratory polyarthritis involving not only joints but also bursae and tendons. This usually rapidly evolves into a monoarticular process, although polyarticular processes are reported, involving the knee, ankle, or wrist. Patients usually present during the monoarticular phase. The arthritis is similar to other inflammatory processes of the joint and produces warmth, erythema, swelling and pain upon motion of the joints; however, it is usually not as severe as in a suppurative joint. Effusions may be large and generally recur following aspiration. The history of a rash is often overlooked by patients, and the arthritis usually presents within 6 months of the erythema migrans lesion. If the arthritis is untreated, the arthralgia lasts approximately 1 week. In the following 3 months, two thirds of the patients will have recurrences and approximately 10% of these patients will develop a chronic arthritis, usually involving the knee. This may last several years; however, this is usually not a destructive process. Confirming a septic arthritis is often best done by cultures; however, cultures of synovial fluid in Lyme arthritis are usually ineffective. The most widely used test to diagnose Lyme disease is serum antibody titers. Synovial fluid analysis usually reveals an inflammatory process, with WBC counts ranging from 500 to 98,000 cells/mm³. Lyme arthritis can be treated with oral doxycycline for 30 days. If this is unsuccessful, patients can be retreated with the same oral regimen for another 30 days or the antibiotic can be changed to IV ceftriaxone for 14 to 30 days.

### Septic Arthritis in Patients with Existing Joint Disease

Patients with underlying joint disease are more likely to develop septic arthritis than patients with normal joints. This is especially true for patients with rheumatoid arthritis and crystalline arthritis. In patients with rheumatoid arthritis, septic arthritis is more likely to be polyarticular and more likely to result in complications. In patients with the crystalline arthropathies, neutrophil invasion secondary to septic arthritis also leads to increased precipitation and release of crystals. Therefore, the clinician who discovers crystals on joint fluid aspiration should not abandon the search for an infectious agent.

Surgical implantation of a joint prosthesis is followed by joint infection in 1 to 5% of cases. The infection is most likely to occur in the first 3 months (50% of cases) after surgery and may be due to bacterial contamination during surgery, spread from a contiguous wound infection, or spread from hematogenous seeding. The prosthesis and cement are foreign bodies and are ideal sites for bacterial colonization. The most common infectious agents are *S. epidermidis* (40% of cases), *S. aureus* (20%), and streptococcal species (20%). The predominant symptom is pain in the joint, and unlike the pain from a loose prosthesis, it is constant and present at rest. The clinical course is variable. With *S. epidermidis* infections, the course is usually indolent. With *S. aureus*, a more aggressive infection occurs, with more pronounced inflammation, effusion, and systemic symptoms. Radiographic changes that may signify a prosthetic joint infection include widening and lucency of the bone-cement interface to greater than 2 mm, movement of the prosthesis, periosteal reaction, and fractures through the cement. Aspiration may be more difficult in this situation because of scarring and alteration of the joint space. Joint aspiration reveals infection in a prosthetic joint in more than 85% of patients. Patients with prosthesis joints who are undergoing invasive oropharyngeal or genitourinary procedures require antibiotic prophylaxis.
Septic arthritis can be particularly difficult to diagnose and treat if it occurs in fibrocartilaginous joints such as the sternoclavicular, acromioclavicular, and sacroiliac joints and the symphysis pubis. Septic arthritis of the axial skeleton, especially of the sternoclavicular joint, is commonly seen in IVDUs, with *Pseudomonas* as a common infecting agent. In patients who do not have other predisposing factors, the most common bacterial causes are *S. aureus* and *S. epidermidis*. The presentation is usually pain and point tenderness over the involved joint. Fever and an elevated ESR are commonly reported, although they are not always present due to the suppressed immune status of the patient. Bone scans may be able to detect the infected joint but are less useful in establishing a diagnosis in the ED setting due to the time required to complete the scan. CT and MRI are more timely in making the diagnosis and are very helpful in diagnosing septic arthritis in the fibrocartilaginous joints.

**Differential Diagnosis Considerations of Septic Arthritis**

Many disease processes can be confused with septic arthritis. Metaphyseal osteomyelitis may mimic septic arthritis because the adjacent joint may develop an effusion. The two infections can be concurrent. Juvenile rheumatoid arthritis is usually more gradual in onset and produces polyarticular arthritis in children less than 16 years old but may present as a monoarticular process that mimics septic arthritis. Toxic or transient synovitis is another inflammatory process in children that can be confused with septic arthritis. It occurs in the 3-month to 6-year age range, usually affects the hip, and is a self-limited disease with no long-term morbidity. It may be more common after upper respiratory infections. Children with transient synovitis have less pain with passive joint motion than patients with septic arthritis, do not usually have a fever or appear ill, but tend to favor the unaffected leg as in septic arthritis. Diagnostic evaluation typically reveals a normal WBC count and ESR and no radiographic abnormalities. However, the only way to reliably differentiate between toxic synovitis and septic arthritis in the hip joint is to obtain synovial fluid for analysis, and this is usually done under ultrasound guidance.

Other diseases of the hip in children that are included in the differential diagnosis are Legg-Calvé-Perthes disease (avascular necrosis of the femoral head) and slipped capital femoral epiphysis; however, these processes are not as acutely disabling as septic arthritis. Rheumatic fever commonly presents with a migrating polyarthritis and may mimic gonococcal bacteremia. Patients with Lyme arthritis are not as debilitated as those with septic arthritis, but in endemic areas, antibody titers should be obtained.

In the adult, osteoarthritis, gout, and pseudogout may yield joint examination findings that are similar to those of septic arthritis. Other arthropathies in the differential diagnosis of septic arthritis are Reiter's syndrome, psoriatic arthritis, arthritis associated with inflammatory bowel disease, and ankylosing spondylitis. Collectively, these are known as the seronegative spondyloarthropathies. Trauma to the joint can produce synovitis and hemarthrosis, which may be mistaken for septic arthritis. In a patient with hemophilia, hemarthrosis causes joint inflammation and destruction, and there may be superimposed infection.

Reactive arthritis has traditionally been considered a sterile inflammatory response to a distant infection. However, recent data suggest that antigens from the infectious trigger are often present in the joint. Several viral and bacterial microorganisms can produce reactive arthritis. The most recognized syndrome is post-streptococcal reactive arthritis. Some other common organisms to cause reactive arthritis are *Chlamydia*, *Salmonella*, *Shigella*, *Borrelia burgdorferi* (Lyme disease), *Yersinia*, human T-cell lymphotropic virus type 1, rubella virus, hepatitis B virus, adenoviruses, parovirus, and Epstein-Barr virus. In reactive arthritis, host factors rather than microbial aggression account for most of the inflammatory process. The pathogenesis of reactive arthritis involves deposition of immune complexes in the joint, persistence of organisms in the joint, and stimulation of the immune system. Strong evidence exists to support a link between the susceptibility to reactive arthritis and the HLA-B27 human leukocyte histocompatibility antigen. Reactive arthritis can usually be distinguished from septic arthritis because it tends to involve multiple joints in a migratory pattern. The inflammatory process is also less severe with reactive arthritis. There is less effusion, the joint is not as hot or tender as it is with septic arthritis, and joint fluid cell counts are usually below 50,000/mm³.

**Management of Septic Arthritis**

Septic arthritis is an orthopedic emergency, and empirical antibiotics should be promptly administered if the diagnosis is strongly suspected. Considerable disagreement exists regarding medical versus surgical joint decompression, and a number of patient factors need to be evaluated before a decision is made. Medical management includes needle aspiration of the joint. If pus reaccumulates, repeat aspiration is performed. The only situation in which antibiotics alone can adequately treat a septic joint is in gonococcal septic arthritis. After the diagnostic joint aspiration, almost all cases of gonococcal septic arthritis will quickly resolve with antibiotics alone. Surgical drainage is accomplished by arthrotomy or arthroscopy. Surgical drainage may involve the placement of tubes in the joint that can be used for irrigation and drainage.

Although needle aspiration may be adequate treatment for most septic joints, surgical drainage is usually necessary in at least two settings. Septic arthritis of the hip, especially in infants and children, is accompanied by rapid destruction of the joint if drainage is not quickly performed. Needle aspiration is often ineffective in this situation, and arthrotomy is the treatment of choice for infected hips. Some experts recommend a similar approach with a septic shoulder. Patients with joint prosthetics represent another population where the surgeon must be involved early. Once a joint prosthesis is infected, the implants are removed, and the infection needs to be treated and cleared. After this is accomplished, a new prosthetic can be installed.

Patients with a surgical implant in whom septic arthritis is suspected should not undergo aspiration in the ED. Aspiration is best done in the sterile environment of the operating room in order to avoid introducing infection.

The selection of antibiotics for the treatment of septic arthritis is outlined in Table 134-1. In most cases the emergency physician does not know the identity of the causative organism, but treatment must be tailored to the most likely causative agents based on the patient’s age and immune status. *S. aureus* remains the predominant pathogen for all age groups, and unless gonococcal arthritis is confirmed, antibiotic selection should always include an antibiotic that has excellent bactericidal activity against *S. aureus*. Gonococcal septic arthritis is the most common cause of arthritis in young adults. Penicillin- and fluoroquinolone-resistant strains are becoming more prevalent, and a third-generation cephalosporin is the best choice for gonococcal arthritis. In elders, gram-negative septic arthritis is more common, and agents such as the
third-generation cephalosporins and aminoglycosides are added to the antistaphylococcal regimen. Establishing good bactericidal serum levels of antibiotics will ensure that the levels in joint fluid are also bactericidal.4,8,14,26,124

Disposition of the Patient with Septic Arthritis

Any patient suspected of having septic arthritis requires joint aspiration. In some cases the initial culture results, Gram’s stain, and cell counts make the diagnosis of septic arthritis extremely likely. The patient should be given an initial parenteral dose of antibiotics in the ED and admitted for continued management. Consultants will then determine the need for further drainage procedures. If cultures of the synovial fluid are negative but the clinical appearance strongly suggests septic arthritis, the patient should be treated with appropriate antibiotics and admitted to the hospital. If the joint fluid aspirate is not consistent with septic arthritis and clinical findings are equivocal, the patient can be discharged from the ED and reevaluated in 24 hours. In immunosuppressed patients, patients with preexisting joint disease, and patients with joint replacements, septic arthritis can be difficult to detect. A conservative approach with in-hospital observation and treatment is indicated if there is any possibility of septic arthritis in these patients.

In most cases the prognosis for the patient with septic arthritis is favorable. Two thirds of afflicted patients can expect to recover completely and achieve full, painless range of motion of the afflicted joint. In approximately one third of cases there is decreased mobility or ankylosis, pain on joint movement, chronic infection, or overwhelming sepsis and death. Those patients most likely to do poorly include those who have a delay in diagnosis and treatment, patients with underlying joint disease, especially rheumatoid arthritis, those with polyarticular septic arthritis, and those who have positive blood cultures.4 Despite many advances in diagnosis and treatment, the overall morbidity for patients with septic arthritis has not decreased in the past 2 decades. A general rule is that if the diagnosis of septic arthritis is made and treatment is initiated within 1 week of the onset of symptoms, the outcome is almost always favorable. Delays beyond 1 week are associated with worse outcomes. Diagnosis and rapid treatment of septic arthritis prove to be most elusive in two groups of patients: infants and people with existing joint disease. In infants and children, early symptoms can be nonspecific and difficult to assess; consequently, children with septic arthritis, especially of the hip, who experience a delay in diagnosis and treatment have a disappointingly high rate of complications. In patients with existing joint disease, septic arthritis may be mistaken for an acute exacerbation of their underlying disease process and ED physicians must remain vigilant in their pursuit of the correct diagnosis.4,8,14,116

OVERVIEW

Soft tissue infections run the gamut from mild superficial infections that require only “tincture of time” to infections that will quickly result in death without immediate diagnosis and resuscitation. Unfortunately, the literature on soft tissue infections is often confusing with respect to definition and therapy, in part because the nomenclature has been based on individual names, anatomic areas, or events (e.g., postsurgical gangrene). The clinical characteristics of soft tissue infections often overlap (Table 135-1) as they evolve from superficial to deep. In addition, the bacteriologic spectrum can change with time, and thus the clinical manifestations, including systemic symptoms, may be altered. A patient does not strictly have to have an abscess, a cellulitis, or a fasciitis, but can have all of them at any time. A good rule of thumb is that the deeper the soft tissue infection is, the more normal the skin surface appears.

CELLULITIS

Perspective

Cellulitis is a soft tissue infection of the skin and subcutaneous tissue usually characterized by erythema, swelling, and tenderness. Cellulitis can be acute, subacute, or, on rare occasions, chronic. Trauma, or breaks in the protective cutaneous skin layer, may be a predisposing cause, but hematogenous and lymphatic dissemination can account for its sudden appearance in previously normal skin.

Principles of Disease and Clinical Features

The signs and symptoms of cellulitis are generally pain or tenderness, erythema that blanches on palpation, swelling of the involved area, and local warmth. Without therapy, it will spread in a radial fashion both distally and proximally with associated swelling. Cellulitis occurs most often in the lower extremities, then upper extremities, and the face. Staphylococcus aureus and Streptococcus pyogenes are by far the most commonly isolated organisms. In children, Haemophilus influenzae type B in children. This cellulitis is usually associated with high fever and white blood cell counts greater than 15,000/mm³, with a left shift. Fortunately, the incidence of such infections in children has decreased with the advent of an effective vaccine.

In general, the bacterial cause of cellulitis is a reflection of the bacteria found on the skin or mucous membranes of the anatomic site involved. Ludwig’s angina is a cellulitis of the submandibular spaces bilaterally. This deep soft tissue infection caused by oral flora may quickly result in respiratory distress by causing swelling and subsequent elevation of the floor of the mouth and the tongue. Odontogenic infection, especially of the second and third lower molars, is the most common origin of Ludwig’s angina. Approximately 80% of patients offer a history of recent dental work or tooth pain. Cellulitis around the perineum is often due to anaerobes or fecal flora and may spread rapidly through the soft tissues, producing a necrotizing fasciitis.

Differential Considerations

Other conditions simulate the appearance of bacterial cellulitis, including arthropod and marine envenomation, the inflammatory response to foreign bodies, healing or postsurgical wounds, chemical or thermal burns, septic or inflammatory joints, osteomyelitis, dermatitis, and the arthritides. Differentiation, especially if the process is early and localized, may be difficult. In nonbacterial cellulitis, the inflammation tends to stay localized and is often less tender to palpation.

In bacterial cellulitis, lymphangitis and local lymphadenopathy may be seen. Flucluant, if present, signifies abscess formation; however, the absence of fluctuance does not rule out abscess. Fever is uncommon and should prompt the physician to consider secondary bacteremia or systemic involvement. With local involvement, vital signs, other than a slight tachycardia, are usually normal. Unless there is systemic involvement, white blood cell counts are usually normal or mildly elevated with little or no shift to the left. One exception is H. influenzae type B in children. This cellulitis is usually associated with high fever and white blood cell counts greater than 15,000/mm³, with a left shift. Fortunately, the incidence of such infections in children has decreased with the advent of an effective vaccine.

Diagnostic Strategies

Bacterial cultures of material obtained by direct needle aspiration of the area of cellulitis, either in the area of greatest erythema intensity or at the leading edge, are not helpful when no purulence is present. A recent study of needle aspiration of cellulitis indicated that only about 10% of the time is the...

Management

The time-honored treatment for cellulitis includes immobilization, elevation, heat or warm moist packs, analgesics, and antibiotics. Studies do not document any difference in morbidity or resolution with this regimen versus the use of antibiotics alone.

When managing a patient with cellulitis, the emergency physician must attempt to identify the cause. Trauma, puncture wounds, breaks in the skin, lymphatic or venous stasis, immunodeficiency, and foreign bodies are all predisposing factors. Hematogenous or contiguous spread from nearby infected tissue is an uncommon cause. Most patients will respond to appropriate oral antimicrobial agents. Cellulitis in the area of edema from venous or lymphatic stasis is often difficult to manage and may need aggressive parenteral antibiotic therapy. Secondary bacterial overgrowth occurs commonly in these circumstances.

Disposition

Localized cellulitis of an extremity in an immunologically intact, afebrile patient can be treated on an outpatient basis with oral antibiotics. Follow-up is indicated within 24 to 48 hours if the erythematous area is not diminishing in size or if fever or systemic symptoms develop. Methicillin-resistant *Staphylococcus aureus* (MRSA) as a causative organism in cellulitis is increasingly a concern, even in community acquired infections. For outpatient management of cellulitis, the suggested agents are shown in Table 135-2. When community-acquired MRSA is considered, trimethoprim-sulfamethoxazole, clindamycin, or tetracyclines can be used as first-line treatment, holding agents like linezolid and vancomycin in reserve for refractory cases. Patients whose cellulitis continues to worsen after 48 to 72 hours of appropriate outpatient therapy should be treated with parenteral antibiotics. This can sometimes be achieved on an outpatient basis with home health agency assistance, reducing costs and risk of nosocomial infection. Inpatient management with parenteral antibiotics and closer observation are indicated in patients with systemic toxicity, and with severe infections involving significant portions of an extremity (particularly the hands and feet), the head and neck, or the perineum. All patients with cellulitis should be monitored closely to ensure that the process is resolving. Patients who are immunocompromised, including those who are diabetic, alcoholic, on chemotherapy or steroid therapy, asplenic, or at extremes of age, require aggressive monitoring and treatment.

Patients do not have a simple cellulitis if they have a fever, hypotension, confusion, crepitus, or bullae formation of the involved soft tissues. These patients may be septic, with infectious seeding to other sites such as blood, bone, lung, solid organs, or brain. They may have deep soft tissue infections necessitating aggressive surgical débridement. If an infection spreads to deeper tissues, either directly or through lymph or blood with distal seeding, the initially localized superficial infection can quickly evolve into a severe systemic illness. Patients with these symptoms should be hospitalized and evaluated for deep soft tissue infections and systemic bacteremia.

Special Types of Cellulitis

**Periorbital (Preseptal) and Orbital Cellulitis**

**Perspective**

Cellulitis of the central face involving the area of the orbits must be treated aggressively. The venous drainage of that area is through communicating vessels into the brain via the cavernous sinus. Streptococcal species are currently the most common infecting organisms. The incidence of cellulitis and other infections from *H. influenzae* has decreased from...

*Methicillin-resistant strains require treatment with alternate antibiotics such as vancomycin, linezolid, daptomycin, and others. Combination therapies may be necessary. Trimethoprim-sulfamethoxazole may be effective against some strains. There is no clearly accepted therapy for vancomycin-resistant strains; combinations of the above drugs with other antimicrobials may be effective. Single-drug therapy should be avoided to decrease the development of resistance.

MRSA, methicillin-resistant *Staphylococcus aureus*.

previous prominence due to the advent of an effective vaccine.15–17

**Principles of Disease and Clinical Features**

Periorbital (preseptal) cellulitis is an infection lying anterior to the orbital septum. It is usually associated with swelling of the eyelid, discoloration of the orbital skin, redness, and warmth. Conjunctival ecchymosis and infection with occasional discharge, fever, and leukocytosis are present. Vision, extraocular movements, pupillary findings, and optometric examination findings are normal.

Orbital cellulitis tends to have similar but more severe symptoms than preseptal cellulitis. Patients with orbital cellulitis may have proptosis, decreased ocular mobility, ocular pain, and tenderness on eye movement. Retro-orbital gas or abscess formation increases the severity of these findings and results in decreased visual acuity; it can be detected with computed tomography or magnetic resonance imaging.

Both orbital and periorbital cellulitis tend to be associated with young age and to be unilateral. There is a strong associa-

**Diagnostic Strategies**

Differentiation of periorbital (preseptal) from orbital cellulitis is an important clinical decision that affects management and prognosis. If orbital cellulitis is suspected, a computed tomography scan of the orbit is the most useful aid to determine retro-orbital involvement.20 Sinus and orbital radiographs tend to be less specific.21 Causative organisms now are predominantly *Streptococcus* species, but *S. aureus, H. influenzae*, and anaerobes are also occasionally identified.16,17 Blood cultures and lumbar punctures are indicated in those patients with high fevers or those showing signs of meningismus or sepsis.

**Management**

Early periorbital (preseptal) cellulitis may be followed on an outpatient basis for the first 24 to 48 hours of antibiotic therapy, with daily follow-up to determine whether resolution is occurring. A broad-spectrum antistaphylococcal agent will provide appropriate coverage. Treatment for orbital cellulitis includes hospitalization, intravenous antibiotics, and, in some cases, incision and drainage. Indications for operative intervention include clinical deterioration on antibiotics, the presence of a foreign body as the cause of the infection, and the presence of an abscess.18,19,21,22 Broad-spectrum antibiotic coverage of *H. influenzae, S. aureus, S. pyogenes*, and anaerobes is indicated.4,20

**Streptococcal Cellulitis**

**Principles of Disease and Clinical Features**

Streptococcal cellulitis, often termed *ascending cellulitis*, is usually seen after surgery or trauma but can occur with no predisposing event. The cause may be as subtle as a break in the skin around the webs of the fingers or toes. Ascending cellulitis usually progresses rapidly with prominent lymphangitic streaking and a swollen extremity. Untreated patients can quickly become toxic.

**Management**

Treatment includes the use of an antistreptococcal agent along with elevation of the involved extremity and warm soaks.

**Erysipelas**

**Principles of Disease and Clinical Features**

Erysipelas is an acute superficial cellulitis characterized by a sharply demarcated border surrounding skin that is raised, deeply erythematous, indurated, and painful. It usually involves the dermis, lymphatics, and most of the superficial subcutaneous tissue. Erysipelas most often occurs in the very young and in 50- to 60-year-olds and is associated with small breaks in the skin, nephrotic syndrome, and postoperative wounds. Patients usually appear toxic, with a prodrome of fever, chills, and malaise preceding the eruption of a bright red cellulitis predominantly on the lower extremities or on the
face. Streptococci are the predominant pathogenic organism in erysipelas, including *S. pyogenes* (58–67%), *Streptococcus agalactiae* (3–9%), and *Streptococcus dysgalactiae* (14–25%). Other bacteria are also found in some patients, such as *S. aureus*, *Pseudomonas*, and enterobacteria. The leg is involved in erysipelas 90% of the time, but the arm (5%), the face (2.5%), and the thigh can also be involved.

**Management**

Treatment of erysipelas includes elevation of the infected part, treatment of the portal of entry, if any, and antibiotic therapy. Penicillin G continues to be a standard treatment, but amoxicillin can also be used for 10 to 20 days. Macrolides, cephalosporins, and fluoroquinolones have been shown to be more effective but should be reserved for complicated cases.

**Staphylococcal Cellulitis**

**Principles of Disease and Clinical Features**

*Staphylococcus aureus* produces various toxins that result in local and systemic effects. Tissue invasion, blister formation, and inflammation are caused by toxins such as alpha toxin, hyaluronidase, fibrinolysin, various proteases, and pyrogenic toxin superantigens. Staphylococcal cellulitis is usually an indolent infection. The patient often appears less toxic than with streptococcal cellulitis, and the lesions usually appear more localized and are more likely to result in the formation of an abscess.

**Management**

Antistaphylococcal agents are indicated, along with heat, immobilization, elevation, and incision and drainage, if an abscess is present. With increasing prevalence of community-acquired MRSA, coverage for this organism should be considered in antibiotic selection. Trimethoprim-sulfamethoxazole may be effective agents. Where available, local antibiotic resistance patterns may be helpful.

**Staphylococcal Scalded Skin Syndrome**

**Principles of Disease and Clinical Features**

Staphylococcal scalded skin syndrome, also called staphylococcal epidermal necrosis, is caused by an exfoliative toxin produced by phage group II, type 71 staphylococci. This toxin is a serine protease that acts specifically on the Desmoglein 1 (Dsg1) protein in the zona granulosa of the superficial epidermis to produce a separation that results in widespread painful erythema and blistering of the skin. The syndrome usually occurs in children between the ages of 6 months and 6 years. The mortality rate is approximately 3% in children but reaches 50% in adults and up to 100% in adults with underlying systemic disease. Mucous membranes are usually not involved. Nikolsky’s sign, the easy separation of the outer portion of the epidermis from the basal layer when pressure is exerted, is often present. The skin lesion is characterized by the formation of bullae and vesicles leading to the loss of large sheets of superficial epidermis. The resultant appearance is that of scalded skin.

**Differential Considerations**

The primary differential diagnosis is toxic epidermal necrolysis. Toxic epidermal necrolysis is a full-thickness epidermal necrosis that starts on acral sites and involves mucous membranes. There is also usually a history of drug ingestion with toxic epidermal necrosis, and Nikolsky’s sign is positive only on the lesions. In staphylococcal scalded skin syndrome, unaffected skin also has a positive Nikolsky’s sign. Staphylococcal scalded skin syndrome usually responds to antibiotics. Toxic epidermal necrolysis has no curative treatment and is associated with up to a 50% rate of mortality.

**Diagnostic Strategies**

The diagnosis is based on clinical, histologic, and microbiologic findings, including (1) a clinical pattern of tenderness, erythema, desquamation, or bullae formation; (2) histopathologic evidence of intraepidermal cleavage through the stratum granulosum; (3) isolation of an exfoliative exotoxin producing *S. aureus*; and (4) the absence of pemphigus foliaceus by immunofluorescence. Blister fluid and the skin are usually sterile because this syndrome is toxin generated. *S. aureus* may be cultured from mucous membrane sites such as the oral and nasal cavity.

**Haemophilus influenzae Cellulitis**

**Principles of Disease and Clinical Features**

*Haemophilus influenzae* cellulitis is usually seen in children younger than 5 years and occurs primarily on the face or the extremities. The skin often appears red with a violaceous tinge. The patient appears acutely ill, often with a high fever, a white blood cell count greater than 15,000/mm³, and a high incidence (75-90%) of positive blood cultures. With widespread *H. influenzae* type B immunization, there has been a dramatic decrease in the incidence of *H. influenzae* skin infections.

**Management**

Treatment is parenteral antibiotics with a second- or third-generation cephalosporin followed by ampicillin/clavulanic acid for a total of 10 to 14 days.

**Gram-Negative and Anaerobic Cellulitis**

Gram-negative and anaerobic cellulitis usually occur in the immunocompromised patient. Cellulitis is seen most often around mucous membranes, primarily the perineum and in chronic wounds that are not kept clean and thus become superinfected. The diagnosis requires culturing the causative organism. Aggressive débridement and broad-spectrum antimicrobial coverage are indicated.

---

**TOXIC SHOCK SYNDROME**

**Staphylococcal Toxic Shock Syndrome**

**Perspective**

Toxic shock syndrome often occurs in menstruating women who use vaginal tampons. Although prevalent in the early 1980s, the incidence of toxic shock syndrome has decreased...
Toxic Shock Syndrome: Criteria for Diagnosis

| Fever of 38.9°C (102°F) or higher |
| Rash (diffuse macular erythema) that resembles the rash of scarlet fever |
| Desquamation of skin 1 to 2 weeks after onset of disease |
| Hypotension (systolic blood pressure <90 mm Hg, orthostatic drop of 15 mm Hg or more, or orthostatic dizziness of syncope) |

Clinical or laboratory abnormalities in at least three organ systems:
- Gastrointestinal: nausea and vomiting, diarrhea
- Muscular: myalgia or creatine phosphokinase at least two times normal level
- Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia
- Renal: blood urea nitrogen or creatinine level at least twice normal or pyuria greater than five cells per high-power field
- Hepatic: bilirubin, serum transaminases at least twice normal level
- Hematologic: thrombocytopenia, less than 100,000/mm³
- Neurologic: disorientation or altered consciousness without focal findings
- Reasonable evidence for the absence of other cause of illness

Principles of Disease and Clinical Features

In menstruating women with toxic shock syndrome, *S. aureus* is isolated more than 90% of the time. The clinical manifestations are mainly due to the exfoliative exotoxin produced by *S. aureus*. This is the same exotoxin produced in bullous impetigo, but toxic shock syndrome results from systemic circulating exotoxin, whereas the localized blistering in bullous impetigo is caused by a direct *S. aureus* inoculum. The exotoxin in both cases has exquisite specificity in causing loss of desmosome-mediated cell adhesion within the superficial epidermis only. Other clinical features include fever, a “sunburn/sandpaper” rash, hypotension, and abnormalities in at least three organ systems. Mucosal inflammation, myalgia, profuse watery diarrhea, and changes in mental status are common (Box 135-1). Differential diagnosis includes Rocky Mountain spotted fever, streptococcal scarlet fever, Kawasaki syndrome, and leptospirosis.

Management

Treatment includes early goal-directed therapy for sepsis (i.e., restoration and maintenance of adequate central venous pressure and mean arterial pressure, maintaining central venous oxygenation, and achieving adequate urine output). This may consist of central venous pressure monitoring to direct aggressive fluid resuscitation and the use of alpha- and betadrenergic vasoactive agents. Intravenous antibiotics that cover for penicillinase-producing staphylococci, such as nafcillin or oxacillin, can be used when there is low probability for MRSA. Clindamycin and vancomycin are acceptable for patients who are allergic to penicillin and to provide adequate MRSA coverage. Source control is a key component of management: tampons and foreign bodies must be removed, focal areas of infection drained, and mucous membranes and other sources cultured for the offending pathogen.

Streptococcal Toxic Shock Syndrome

Perspective

*Streptococcus* has long been known to cause invasive infections. Previously, these infections occurred most commonly in patients with compromised immune systems. Since the mid-1980s, however, a streptococcal toxic shock–like syndrome has been described worldwide in younger otherwise healthy patients with serious soft tissue infections. Streptococcal toxic shock syndrome was first described by Cone in 1987 when he reported two cases of shock due to isolated *S. pyogenes* soft tissue infections and postulated a toxin responsible for the shock state. Stevens further characterized the syndrome in 1989 as involving otherwise healthy young patients who presented in shock or progressed to a shock state within 4 hours of admission. These facts seem to indicate an increased virulence of group A alpha-hemolytic *Streptococcus*. Also, although these cases are predominantly caused by Lancefield group A strains, other groups have also been shown to cause streptococcal toxic shock syndrome.

Principles of Disease and Clinical Features

The route of pathogen entry is unknown in up to 50% of cases, with others related to surgery, minor nonpenetrating trauma resulting in hematoma or muscle strain, skin superinfection, or viral infections. In children, streptococcal toxic shock syndrome most commonly follows chickenpox. There is also an association with the use of nonsteroidal anti-inflammatory drugs, which may mask presenting symptoms, resulting in delayed presentation and increased severity of disease.

Patients commonly present with pain, which is severe, abrupt in onset, and may be present prior to the onset of tenderness or other physical findings. Though usually in an extremity, the pain may mimic pelvic inflammatory disease, pneumonia, acute myocardial infarction, peritonitis, or pericarditis. A minority of patients will present with influenza-like symptoms of fever, chills, myalgias, and diarrhea.

Fever is the most common presenting physical sign. However, if shock is present, the patient may be hypothermic. Tachycardia and hypotension are also frequent signs. Most patients also have evidence of soft tissue infection: swelling, erythema, bullae, or tenderness. A scarlet fever–like rash is commonly seen (Box 135-2). These patients often have renal and respiratory failure. The hemodynamic compromise seen in affected patients suggests a cardiotoxic effect of the streptococcal toxins, resulting in normal to low cardiac output, normal systemic vascular resistance, and a reduced left ventricular stroke work index. Mortality ranges from 33 to 81%. The virulence of these infections is attributed to surface proteins, toxin production, and host factors. Streptococcal strains that produce M protein seem to be associated with overwhelming infection. M protein binds to complement control factors and other host proteins to prevent activation of the alternate complement pathway and thus evade phagocytosis and killing by polymorphonuclear neutrophil leukocytes. Extracellular toxins, including superantigenic streptococcal pyrogenic exotoxins, contribute to tissue invasion and initiate the cytokine storm believed to be responsible for illnesses such as necrotizing fasciitis and the highly lethal streptococcal toxic shock syndrome. The toxins act as superantigens to
activate a large population of T cells, bypassing the antigen presentation phase and liberating massive amounts of cytokines, tumor necrosis factor alpha, interleukin-1, and interleukin-6. These cytokines induce the clinical signs of fever, hypotension, shock, rash, and ultimately multiorgan failure. Lack of host antibodies to the surface proteins and toxins will predispose to infection and increased virulence.

Differential Considerations

Differential diagnosis includes staphylococcal toxic shock syndrome and gram-negative sepsis. Patients with *Staphylococcus* infection are unlikely to show cutaneous involvement or extremity pain, may demonstrate a “strawberry tongue,” rarely have soft tissue destruction, and have a lower incidence of bacteremia. Endotoxic shock is differentiated by high cardiac output with lowered systemic vascular resistance and a left ventricular stroke work index that is not reduced.

Diagnostic Strategies

A creatinine level greater than 2.5 mg/dL indicates renal involvement, which may precede hypotension. Serum creatinine kinase correlates well with deep soft tissue involvement, and increasing values may indicate necrotizing fasciitis or myositis (“flesh-eating bacteria”). Other laboratory test abnormalities include hypoalbuminemia, hypocalcemia, and a sometimes mild leukocytosis with prominent “left shift.” Platelets and hematocrit may be initially normal but drop within 48 hours and may be associated with disseminated intravascular coagulation. Blood cultures are positive 60% of the time, and wound cultures are positive in 95% of cases.

Management

Patients with streptococcal toxic shock syndrome require hospitalization for care, usually initially into an intensive care setting. Early goal-directed therapy for sepsis as described above for staphylococcal toxic shock syndrome is a mainstay of treatment. Even with appropriate antibiotic therapy and intensive supportive care, the mortality rate for this disease is 30 to 70%.

It is often difficult to determine initially whether *Streptococcus* or *Staphylococcus* is the offending bacterium, so coverage for both is necessary. Suggested regimens include penicillin plus clindamycin, erythromycin, or ceftriaxone plus clindamycin. Penicillin is only moderately effective against the large inoculum of slow-growing *Streptococcus* seen in necrotizing fasciitis or myositis. A recent retrospective study confirms that clindamycin may work better than β-lactams for streptococcal toxic shock syndrome. Drugs like clindamycin seem to work by two mechanisms: (1) by more effective killing of *S. pyogenes* organisms and (2) by decreasing production of extracellular products that play a role in the pathogenesis of systemic toxicity and/or tissue destruction. Because clindamycin-resistant strains of *S. pyogenes* have been reported in some localities, the presumptive selection of a combination of clindamycin and a β-lactam antibiotic would be prudent in the initial treatment of invasive streptococcal disease. Early surgical débridement may be life-saving, and consultation is appropriate as soon as the possible need for surgical intervention is considered.

Intravenous gamma globulin remains experimental despite some reports of success. Gamma globulin preparations contain antibodies to staphylococcal toxins with some cross-reactivity to streptococcal toxins. A recent comparative observational study showed a benefit for intravenous immunoglobulin in the treatment of streptococcal toxic shock syndrome. Dosing was 2 g/kg, repeated 48 hours later if the patient was unstable. A randomized, controlled trial showed a trend toward decreased mortality for the arm treated with intravenous immunoglobulin, but the study had to be stopped before significance was reached owing to slow enrollment. Dosing in that study was 1 g/kg on day 1, and 0.5 g/kg on days 2 and 3.

Currently, antibiotic prophylaxis is not recommended for household contacts of patients with this disease, although contact with an infected person increases carrier rates in the young. Elders are at increased risk for invasive disease after an infectious contact.

**IMPETIGO**

**Perspective**

Impetigo is a superficial infection of the skin caused by group A beta-hemolytic *Streptococcus* and occasionally coagulase-positive *Staphylococcus aureus*. There are two distinct subtypes: impetigo contagiosa and bullous impetigo. Impetigo is communicable and is the most common cutaneous childhood infection. Most cases occur in late summer and early fall, and the incidence is higher in tropical climates.

**Principles of Disease and Clinical Features**

Insect bites, flies, and infected abrasions play a role in the nonbullous form of impetigo. The pathogenesis and epidemiology of this infection are a mystery in that inoculation of normal skin does not produce clinical disease. During outbreaks of impetigo, streptococci usually appear on normal skin several days before spreading to the nose or throat. In contrast, *Staphylococcus* colonization of the nose and throat takes place before the development of skin lesions. Streptococci found on the skin are not the same subtype as those that infect the pharynx.

The lesions of impetigo contagious begin as tiny papules that rapidly develop into vesicles, which quickly progress to pustules that rupture and crust over within 24 hours. The lesions are usually painless but often are pruritic and may coalesce. The crusts are usually thick, amber colored, and crumbly. Cultures of early vesicles, pustules, or crusts usually yield beta-hemolytic streptococci and occasionally *Staphylococcus aureus*. After the fifth or sixth day, the crusts become thicker and reddish brown. The lesions tend to extend in size, clearing
centrally. Lesions are most commonly seen on the legs, with the arms, face, and trunk less commonly affected. Regional lymphadenopathy is common, lymphadenitis is rare, and fever is not usually present.52

Bullous impetigo is most commonly seen in neonates. It starts as a small vesicle that quickly enlarges into a bulla, often 2 to 5 cm in diameter. When a bulla ruptures, it leaves a red base with a varnish-like thin crust and scales. Satellite lesions are frequently seen. Nikolsky’s sign is not present, and the patient is not toxic.53 Bullous impetigo occurs most commonly on the face and trunk. Regional lymphadenitis is rare. These lesions generally heal faster than those of impetigo contagiosa.

**Differential Considerations**

Impetigo of Bockhart is a superficial staphylococcal folliculitis consisting of clusters of small pustules surrounding hair follicles.54 Ecthyma is closely related to impetigo, except that the infection is usually deeper and heals with scarring. The lesions of ecthyma are usually on the legs and begin as a vesicle that ruptures to form a shallow ulcer. Causative organisms are group A beta-hemolytic *Streptococcus* and rarely *S. aureus*. Treatment is 10 to 14 days of penicillin or topical mupirocin.

**Diagnostic Strategies**

The diagnosis is made clinically, since bacteria are usually not seen in the Gram’s stain of vesicular fluid. Certain strains of streptococci are nephritogenic. Post-streptococcal glomerulonephritis is more likely to follow streptococcal pharyngitis than impetigo. In contrast, acute rheumatic fever is not a consequence of impetigo.54 Although serologic findings in streptococcal pyoderma may show increases in antibodies to various streptococcal antigens, primarily anti-DNAase B and antihyaluronidase, the serologic response as measured by antistreptolysin O is usually poor.51 The streptozyme test, which measures several streptococcal antibodies, often gives false-negative results.51

**Management**

Soaks and wet dressings have not proven useful in treating impetigo. Topical antimicrobial agents such as hexachlorophene or povidone-iodine scrubs or washes are of limited usefulness and may result in the development of satellite lesions.52,55,56 First-line treatment of limited impetigo is with topical mupirocin or fusidic acid. Recent systematic reviews state that these topical antibiotics are superior to systemic treatment with erythromycin, as are effective as other systemic antibiotics, and are better tolerated than systemic treatment. Systemic treatment of widespread disease with penicillinase-resistant antibiotics is recommended despite a lack of randomized prospective clinical trials for this subset of patients.55,56 Local resistance patterns should be taken into account when selecting a systemic antibiotic. First-generation cephalosporins or clindamycin may be effective (see also Table 135-2). In some studies, intramuscular benzathine penicillin G is more effective than oral phenoxymethyl penicillin or erythromycin. The addition of topical steroids to topical antibiotic agents does not improve outcome.

Although cultures of early lesions often grow only *Streptococcus*, older lesions may yield *Staphylococcus*. *Streptococcus* seems to be the prime infecting agent, with *Staphylococcus* as a secondary invader. Treatment of impetigo with systemic and topical antibiotics does not prevent post-streptococcal glomerulonephritis, although it clears lesions quickly, reduces local extension and complications such as adenitis, and prevents spread to other individuals.50

In cases of bullous impetigo, some topical antibiotic preparations, such as gentamicin and a mixture of polymyxin, neomycin, and bacitracin, are as effective as a combination of oral and intramuscular benzathine penicillin G. Antistaphylococcal agents such as oral cephalosporins and semisynthetic penicillins are usually very effective. In most cases, for a solitary lesion or just a few lesions, a topical antibiotic alone is reasonable therapy.51

**ABSCESSES**

**Simple Cutaneous Abscesses**

**Perspective**

A cutaneous abscess is a localized collection of pus resulting in a painful fluctuant soft tissue mass surrounded by firm granulation tissue and erythema. Abscesses occur in all areas of the body. Approximately 20% occur in the head and neck region, 25% in the axillae, 18% in the extremities, 25% in the perirectal area, and 15% in the inguinal area. Most patients complain of pain and the presence of a tender fluctuant mass. Although abscesses may be associated with localized erythema and lymphangitis, the presence of fever or systemic toxicity suggests the possibility of deeper tissue involvement or systemic bacteremia.57

**Principles of Disease and Clinical Features**

The cause of localized abscesses depends on the anatomic region involved.58 Abscesses on the extremities tend to be associated with interruptions of the integrity of the protective epithelial layer of the skin caused by minor trauma, such as cuts, abrasions, or needle punctures. Abscesses of the head, neck, and perineal regions tend to be associated with obstruction of the apocrine sweat glands. The incidence of these abscesses increases in adults because the apocrine and sebaceous glands become active after puberty. Perirectal abscesses arise from bacterial spread from the anal crypts. Vulvovaginal abscesses usually result from obstruction of the Bartholin gland duct. Pilonidal abscesses are caused by plugging of small tears in the skin, usually by hairs around the buttock crease.61

Although most abscesses contain bacteria, approximately 5% of abscesses, especially those associated with parenteral drug abuse, are sterile.57 Clinically, sterile abscesses cannot be differentiated from bacterial abscesses. The bacteria in cutaneous abscesses generally reflect the skin flora of the anatomic area of the body that is involved (Table 135-3). The most common bacterium cultured from abscesses in parenteral drug abusers is *S. aureus*, with streptococcal and mixed flora including anaerobes also occurring.52,63 *Eikenella corrodens* is also sometimes seen with head and neck abscesses associated with intravenous drug abuse.64 Anaerobic bacteria, which are known to be part of the normal flora of the skin and mucous membranes, outnumber aerobes 10 to 1 in the oral cavity and 1000 to 1 in the distal colon.65,66 Most abscesses that originate from mucous membranes (e.g., perioral, perirectal, vulvovaginal) are predominately anaerobic. Bacteria from abscesses in areas more remote from the rectum are primarily constituents of the microflora of the skin. *S. aureus* is the most prevalent aerobe found in abscesses that originate from the skin, yet it is isolated in less than one third of cutaneous abscesses and one half of axillary abscesses.57 *S. aureus* is not commonly associated with abscesses that originate from mucous membranes (e.g., perirectal, vulvovaginal).57,67 *Bacteroides fragilis* is one of the
few anaerobes resistant to penicillin.\textsuperscript{68} Bac teroides resistance to other antibiotics has been reported, including cefoxitin, metronidazole, clindamycin, carbapenems, and fluoroquinolones.\textsuperscript{59, 70} This pathogen, which produces \( \beta \)-lactamase, has been associated with more than 50\% of intra-abdominal infections. Although it is the most common gram-negative anaerobic species in human feces, it is found in fewer than 50\% of perineal abscesses.\textsuperscript{71} Escherichia coli and Neisseria gonorrhoeae are rarely found in cutaneous abscesses from any location.

Differential Considerations

Although the development of an abscess is usually an isolated event, recurrent abscesses in the perineal and lower abdominal area may signify the presence of inflammatory bowel disease. Recurring abscesses in the axillae and inguinal areas may represent hidradenitis suppurativa. Finally, recurring abscesses may be associated with immunocompromise such as occurs with neoplasm, corticosteroid therapy, chemotherapy, diabetes mellitus, acquired immunodeficiency syndrome, leukemia, vascular insufficiency, trauma, or thermal injury.

Diagnostic Strategies

Ultrasonography is a useful technique to localize subcutaneous and intramuscular abscesses, differentiate abscess from cellulites, and identify foreign bodies that are not radiopaque.\textsuperscript{61, 71} The examination of Gram’s stain of material from cutaneous abscesses allows a quick identification of the morphotype of the offending pathogen. In general, the Gram’s stain shows one of three patterns: (1) white blood cells without bacteria, which indicates a sterile abscess; (2) a mixed pattern of gram-positive and gram-negative rods and cocci of varied morphotypes, which indicates mixed aerobic and anaerobic infection; and (3) gram-positive cocci in grapelike clusters, diagnostic of \( S. \) aureus infection.\textsuperscript{57}

Management

The treatment of cutaneous abscesses is incision and drainage. Several studies confirm that antibiotics are not indicated in patients with normal host defenses.\textsuperscript{1, 57, 72, 73} Thus, a Gram’s stain and culture are also unnecessary in these patients. In the immunosuppressed patient, Gram’s stain, culture, and antibiotics are indicated. The selection of antibiotics is guided by (1) the flora anticipated at the location of the abscess, (2) the Gram’s stain results, (3) the presence of a feculent odor that is indicative of anaerobes, and (4) culture and sensitivity findings (see Table 135-2).\textsuperscript{57} Incision and drainage are generally painful because local anesthetics are less effective in inflamed acidic locations. The use of parenteral or regional analgesia may be indicated in addition to a local anesthetic agent. Nitrous oxide is an option, especially in a self-administered 50\% concentration. The incision should be deep enough into the abscess cavity to ensure adequate drainage. Elliptical incisions are preferred by some to prevent premature closure of the cutaneous surface. The cavity should be gently curetted to free all loculated areas of pus, and the cavity should be irrigated. A loose packing should be removed within 24 hours or within 24 hours in cosmetically important areas such as the face. Once the packing is removed, warm soaks are recommended three or four times a day for 10 to 15 minutes for 2 to 3 days.\textsuperscript{57}

Furuncle

A furuncle usually evolves from a superficial folliculitis. It is a deep inflammatory nodule surrounded by an intense local tissue reaction. The abscess tends to be very thin walled, and purulence is present. Skin flora (\( S. \) aureus, streptococci) are usually isolated.

Carbuncle

A carbuncle is an extensive process of interconnecting deep abscesses that extend into subcutaneous tissues. The microbes are usually aerobic; however, \( Pseudomonas aeruginosa \) may be present in chronic cases. Predisposing factors include folliculitis, blood dyscrasias, steroids, heavy perspiration, obesity, diabetes, and skin location, such as areas of friction (e.g., the back of the neck).

Hidradenitis Suppurativa

Perspective

Hidradenitis suppurativa is a disease consisting of chronic suppurative abscesses in the apocrine sweat glands. One in

* Cultures with no growth were excluded.

In most cases, the disease manifests as episodic occurrences of one or more painful subcutaneous nodules, associated with burning, itching, local cellulitis, swelling, and a malodorous discharge. These nodules drain spontaneously or are surgically incised with drainage of scant pus. Resolution usually occurs within a few days. In some patients, however, the disease tends to be chronic and extensive, with multiple abscesses, sinus tracts, and fistulas. These often heal with hypertrophic scars and may result in a tender, unsightly area.

Staphylococcus aureus, Staphylococcus viridans, and common skin anaerobes are commonly isolated. Chronic disease often results in overgrowth with fecal flora in the perineum and Proteus with other mixed aerobes and anaerobes in the axillae.

The pathogenesis of this disease is more complex than a simple infection model. Success in treating hidradenitis with immunosuppressive drugs indicates that the disease may be primarily or at least in part an inflammatory process.

Differential Considerations

Hidradenitis suppurativa must be differentiated from a simple cutaneous abscess of the axillary region or perianal and perirectal abscesses. This differentiation is usually accomplished by noting the chronicity of the process, the multiplicity of abscesses, and the lack of involvement with the rectal mucosa.

Management

Although clindamycin alone or in combination with rifampin may provide temporary recession of the disease, the almost inevitable recurrence makes surgery the definitive therapy. Severe cases may improve with immunosuppressive therapy. Incision and drainage usually suffice in an acute situation. Sinus tracts and fistulas should be unroofed, all loculations excised, and all purulence and necrotic tissue evacuated. Subsequent antibiotic coverage is usually unnecessary in patients with normal host defenses and without additional soft tissue involvement. Chronic or extensive disease often requires extensive surgical removal of all hair-bearing skin in the apocrine gland areas. Coverage requires either primary closure, rotated skin flaps, or grafting. Although rare, the most serious complication of hidradenitis suppurativa is squamous cell carcinoma, so pathologic examination of surgical specimens is recommended. Routine colostomy in patients undergoing surgical treatment of perineal disease is usually not necessary, as long as aggressive wound care is instituted. Patients who might benefit from fecal diversion are those in whom proper wound care is not feasible, and those patients suffering from concomitant Crohn’s disease and hidradenitis suppurativa.

Hidradenitis suppurativa has been associated with social, personal, and vocational difficulties because of the chronic, uncomfortable, malodorous, and unsightly nature of the disease. Early referral for surgical obliteration of the apocrine glands should be considered in these patients.

Bartholin’s Cyst Abscess

Principles of Disease and Clinical Features

A Bartholin’s cyst abscess is caused by an obstructed Bartholin duct. The flora is usually a mixture of aerobic and anaerobic flora from the vagina, with Chlamydia trachomatis and N. gonorrhoea cultured approximately 10% of the time. The patient usually has a painful cystic mass on the inferior lateral margin of the vaginal introitus. Signs and symptoms are usually localized, but septic shock can occur in rare cases.

Management

Abscesses should be drained from the mucosal rather than the cutaneous surface. Simple incision and drainage carries a high risk of recurrence, so the cavity should be packed open. The Word catheter is a 10-Fr balloon catheter designed specifically for this purpose and is both convenient to use and highly successful. After incision and drainage, the catheter is inserted and inflated with 2 to 5 mL of water or saline (Fig. 135-1). The catheter should be left in place for 4 to 6 weeks so that a sinus...
**Fasciitis**

**Principles of Disease and Clinical Features**

Fasciitis is an infection of the fascia, subcutaneous tissue, and skin. Erythema, marked edema, and, sometimes, areas of gangrene occur (see Table 135-1). Much confusion has surrounded the nomenclature of these necrotizing infections because they have been named for specific bacteria (e.g., hemolytic streptococcal gangrene), after individuals (e.g., Meleney’s synergistic gangrene), by anatomic appearance (e.g., necrotizing fasciitis), and for specific circumstances (e.g., postoperative bacterial gangrene). By definition, fasciitis does not involve muscle, but it can spread to invade underlying muscle, causing myonecrosis. Patients with fasciitis manifest moderate to severe systemic toxicity, often out of proportion to the cutaneous findings, with high fever, tachycardia, anxiety, disorientation, and often frank shock. Tissue invasion is rapid, often spreading from a cellulitis to a necrotizing fasciitis within 1 to 2 days. Massive subcutaneous edema and necrosis are common. Early on, the skin may be relatively spared, but as the disease progresses, the cutaneous tissues often demonstrate blebs, crepitus, or frank necrosis. Diabetes, peripheral vascular disease, trauma, and recent surgery are predisposing factors. Pain varies because cutaneous nerve endings are quickly destroyed. Thus, the absence or cessation of pain may indicate worsening rather than improvement.

**Management**

The initial treatment of all of these infections involves fluid resuscitation, parenteral antibiotics, and early surgical consultation for incision, drainage, and débridement. Large quantities of crystalloids are often necessary to replace fluid sequestered in the wound. Hemolysis occurs and may require the use of blood replacement products. Disseminated intravascular coagulopathy occurs in severe cases. Intravenous calcium may be necessary to reverse the hypocalcemia that results from necrosis of subcutaneous fat. The usual anaerobic infection has a foul discharge, occurs in locations near mucosal openings (perineum, oral pharynx), may manifest with tissue gas, and often has a Gram’s stain that shows a polymorphic array of organisms with negative aerobic cultures. The initial choice of antibiotics for necrotizing fasciitis should be guided by the Gram’s stain, culture, and anatomic area involved. Use of high-dose penicillin, clindamycin, and an aminoglycoside, third-generation cephalosporin, or fluoroquinolone is recommended for a broad spectrum of coverage of aerobes, gram-negative enteric organisms, and anaerobes. If gram-positive organisms are expected or are seen on stain, a penicillinase-resistant penicillin should be added.

**SPECIFIC FASCITIS SYNDROMES**

**Meleney’s synergistic gangrene** (progressive bacterial synergistic gangrene) involves superficial and deep fascial planes with thrombosis of the subcutaneous vessels and gangrene of tissues. It is usually seen at the site of a laceration or surgical wound, but sometimes no portal of entry can be found. The skin appears erythematous and may eventually take on a dusky, gangrenous appearance. The patient is toxic, with fever and leukocytosis. Group A *Streptococcus* is found on the skin and in the blood, although *S. aureus* and gram-negative enteric organisms can also be found. Treatment is wide incision and débridement and appropriate antibiotics.

**Clostridial cellulitis** (anaerobic cellulitis, local gas gangrene) is a gas-forming infection of the skin and subcutaneous tissue that spreads through intrafascial planes. Other bacterial flora can be seen. Healthy muscle is not involved. It results from superinfection of previously traumatized or necrotic tissue. Gas distributes in large bubbles in the fascial plane but not the muscle. Patients show signs of systemic toxicity: fever, tachycardia, edema of the affected part, and pain. Incision and débridement of involved tissue and blebs are necessary. Antibiotic treatment is penicillin or clindamycin. These patients must be hospitalized.

**Nonclostridial crepitant cellulitis** is similar to clostridial cellulitis except that the flora are usually polymicrobial, with aerobic...
and anaerobic coliforms such as E. coli, Klebsiella, Enterobacter, Peptostreptococcus, Peptococcus, and B. fragilis. These infections tend to progress from a fasciitis to a myositis. The treatment is broad-spectrum intravenous antibiotics and close observation and débridement.96

_Fournier's syndrome_ is an insidious necrotizing subcutaneous infection of the perineum that occurs primarily in men, usually between 20 and 50 years of age, and usually involves the penis or scrotum. The disease occasionally occurs in women, especially in patients who are immunocompromised. Pain or itching in the genitalia is followed by fever, chills, and impressive perineal swelling, which may simulate a strangulated hernia. The inflammation may involve the entire abdomen, back, and thighs. There is frequently crepitance on palpation, indicating subcutaneous gas. Systemic symptoms include nausea and vomiting, changes in sensorium, and lethargy. Eventually, gangrenous areas demarcate and become less painful as destruction and sloughing of sensory nerves occur. The tissue breaks open, sloughs, and gives off an overwhelming feculent odor.

The most common causal factors are infection or trauma to the perianal area, including anal intercourse, scratches, chemical or thermal injury, and diabetes. Local trauma and perianal disease precede approximately one third of all cases. Cultures demonstrate bacteria of the distal colon, with a complex picture of aerobic and anaerobic bacteria. B. fragilis tends to be the predominant anaerobe and E. coli the predominant aerobic.

This bacterial invasion of the subcutaneous tissues of the perineum causes obliteration of the small branches of the pudendal arteries that supply the perineal or scrotal skin, resulting in acute dermal gangrene. This combination of erythema, edema, inflammation, and infection in a closed space stimulates anaerobic growth. Identification of the offending organism can be done with Gram's stain and wound cultures. Emergency management includes antibiotic therapy against anaerobes and gram-negative enterics and wide incision and drainage of the area to remove all the necrotic tissue.96 The mortality rate is approximately 3 to 38%.97

**MYOSITIS**

**Principles of Disease and Clinical Features**

Myositis, or myonecrosis, is a deep soft tissue infection with death of muscle and a variable degree of inflammation of the overlying tissues (see Table 135-1). The skin may show minimal erythema to frank gangrene, but usually the infection is associated with massive edema. Myositis includes gas gangrene (clostridial myonecrosis), nonclostridial myonecrosis, and synergistic necrotizing cellulitis.98

_Clostridial myonecrosis_, or gas gangrene, is a rapidly progressive muscle-necrosing infection, often with little inflammatory skin reaction but with gas formation. It is usually a result of trauma or recent surgical wounds.97 Pathogenesis includes the elaboration of exotoxins by clostridial bacilli. Clostridia are spore-forming anaerobic gram-positive bacilli usually found in the soil and in the intestinal tracts of humans and animals. Clostridia produce a toxin that damages and kills muscle, setting up the anaerobic environment that promotes further growth of the bacilli. The incubation period is 1 to 4 days. The onset of disease can occur in 6 to 24 hours. Pain is the earliest and most important symptom. Tachycardia out of proportion to fever is noted. Temperature is not a reliable index of infection. Mentally, patients are apathetic, with varying levels of stupor and delirium. The wound appearance is striking in the later stages but does not show the usual erythema of a pyogenic cellulitis. Early on, the skin may be white, shiny, and tense, or essentially normal. Progressive swelling can produce a dusky bronze appearance of the skin, with further progression leading to formation of vesicles filled with dark red or purplish fluid. A brown watery discharge with a peculiar, foul "mousy" odor is noted. Crepitus is not a reliable finding, owing to overlying edema. Gas alone in the tissues cannot make the diagnosis of gas gangrene.99 The muscle appears to be cooked or dead and does not bleed when cut or retracted when pinched.

_Nonclostridial myonecrosis_ is similar to gas gangrene, except that the flora include anaerobes such as _B. fragilis_ and _Peptostreptococcus_ along with gram-positive aerobes such as _Staphylococcus_. The prognosis is better than that for patients with gas gangrene. Treatment is appropriate débridement and antibiotic coverage. Gas may be present.96,99

_Synergistic necrotizing cellulitis_ is a rapidly progressive infection usually of the lower extremities and perineum, commonly seen in patients with diabetes or peripheral vascular disease. Systemic manifestations are variable, from minimal to frank shock. The overlying skin often has a "dishwasher" discharge and may show blebs, crepitus, or necrosis. The infection often extends from skin through the muscle. Pain is usually present. The causative pathogens include aerobes, _Streptococcus_, _Staphylococcus_, _Klebsiella_, _Proteus_, _E. coli_, and anaerobes, often _Bacteroides_ and _Peptostreptococcus_. Hemolysis is common and the mortality rate is high. Treatment includes aggressive fluid and blood product resuscitation, appropriate antibiotics, and rapid surgical débridement.83,94

**Diagnostic Strategies**

Gram's stain smears of the area show large gram-positive rods. Radiographs may reveal gas. Where available, magnetic resonance imaging may be helpful if the initial presentation is unclear or nonspecific, to speed diagnosis and reveal the extent of tissue involvement.100

**Management**

Treatment is wide débridement and excision of the wound. Parenteral antibiotics should be given to cover anaerobes and enterics; penicillin in large doses, a cephalosporin, or clindamycin is indicated.98 The mortality rate is high.97 Hyperbaric oxygen therapy may be effective very early in this disease. Hyperbaric oxygen therapy has been advocated for deep anaerobic infections that result in necrotizing fasciitis and myonecrosis, especially by clostridial species. Hyperbaric oxygen therapy is also a consideration in cases of nonclostridial involvement and _Fournier’s syndrome_.101 The definitive benefit of hyperbaric oxygen therapy in necrotizing infections remains unproven.83,96 Hyperbaric oxygen therapy may provide an environment less appropriate for anaerobic growth by reducing the oxygen-reduction potential, decreasing edema via hyperoxic vasoconstriction, enhancing the ability of phagocytes to destroy bacteria, and promoting angiogenesis and subsequent granulation tissue.101

**Acknowledgment**

Drs. Meislin and Guisto would like to acknowledge and thank Drs. Brooke Rosonke and Gregory Gardner for their help and assistance with the writing of this chapter.
Soft tissue infections encountered in the emergency department vary widely in location, severity, and causative organisms. A working knowledge of the usual presentation of specific infections, based on the anatomic area involved and origin (mucosal or skin) of the infection, will allow selection of appropriate empirical antibiotic therapy.

Identification of the infecting organism by culture or other laboratory technique is often unnecessary in common mild to moderate infections and can usually be reserved for severe or unusual cases. Severe or potentially life-threatening bacterial infections mandate immediate administration of the best empirical choice of antibiotics; attempts to identify the exact organism should not delay therapy.

Sepsis Syndromes

Chapter 136

Nathan I. Shapiro, Gary D. Zimmer, and Adam Z. Barkin

**PERSPECTIVE**

**Background**

Sepsis syndrome represents the body’s host response to an infection. The causative agent and the host’s activated inflammatory cascade cause the body’s defenses and regulatory systems to become overwhelmed, leading to a disruption in homeostasis. Tachycardia, tachypnea, fever, and immune system activation are manifestations. If the body is unable to overcome this insult, cellular injury, tissue damage, shock, multiorgan failure, or death may ensue.

In 1992, the American College of Chest Physicians/Society for Critical Care Medicine issued a consensus statement to establish uniform criteria defining the sepsis syndromes. For the first time, this allowed a common nomenclature for disease classification and systematic comparisons across studies of septic patients. The definitions vary. Systemic inflammatory response syndrome (SIRS) is defined as two or more of the following: tachycardia, tachypnea, hyperthermia or hypothermia, high or low white blood cell count, or a bandemia; sepsis is the combination of infection plus SIRS; severe sepsis is sepsis plus organ dysfunction; and septic shock is severe sepsis plus hypotension, defined as a systolic blood pressure less than 90 mm Hg, not responsive to a fluid challenge (Box 136-1).

The importance of the sepsis syndromes is to provide a common nomenclature for disease classification and research purposes. Efforts to validate this classification scheme in the emergency department (ED) population have demonstrated the term sepsis when characterized by fulfilling the SIRS criteria alone is perhaps overly sensitive and nonspecific and does not convey an increased mortality risk, though it should prompt further evaluation. However, the presence of organ dysfunction and shock were shown to be significant predictors of adverse outcome. Newer efforts have proposed the “PIRO” approach to better understand and prognosticate illness. Assessing predisposing conditions, infection source, response of the host, and organ dysfunction will lead to improved classification. Approaching the patient to determine who they are (e.g., underlying comorbidities), what infection they have, how they are responding, and whether organ dysfunction is occurring is a clinically useful and pragmatic way to approach the septic patient.

Bacteremia is often present, but positive cultures are not obligatory in the diagnosis of sepsis. In recent prospective studies, only 17 to 27% of patients with sepsis, 25 to 53% of patients with severe sepsis, and 69% of patients with septic shock actually had positive blood cultures. Culture-negative and culture-positive septic populations have similar outcomes in patients with similar severity of illness. Pneumonia, abdominal abscess with viscus perforation, and pyelonephritis are common primary causes of sepsis. Gram-positive organisms account for 25 to 50%, gram-negative for 30 to 60%, and fungi for 2 to 10% of cases. The distribution varies with the study and, more importantly, with host factors such as the status of the host immune system, patient age, recent hospitalizations, and presence of indwelling vascular catheters.

The health status of the host is a crucial risk factor in the development and progression of sepsis. Elders and those with multiple comorbidities are overwhelmed more easily by systemic infection. Chemotherapy-induced neutropenia, acquired immunodeficiency syndrome, and steroid dependency increase susceptibility to sepsis. Increased use of indwelling devices such as intravascular catheters, prosthesis devices, and endotracheal tubes contribute to the risk of systemic infection and sepsis.

**Epidemiology**

Sepsis is now the 10th most common cause of death in the United States. It is estimated that 571,000 cases of severe sepsis present to U.S. EDs each year. Mortality rates from sepsis are estimated between 20 and 50%. Sepsis accounts for 4 out of 1000 ED visits in the United States. The incidence of sepsis as a reason for hospitalization is rising at a disproportionately high rate among elders, compared to the young (Fig. 136-1). The incidence of sepsis in patients under age 65 years is less than 5 in 100,000, while it is 26 in 100,000 in those 65 or older. The cost of caring for septic patients is estimated to be $17 billion per year in the United States. Hospital discharge data have shown that the incidence of sepsis is increasing as identification improves and the population ages. Estimates have suggested that the incidence will rise 1.5% per annum or more. The number of ED visits for sepsis has risen proportionally with the rise in ED volume over the past 15 years. Recent research has confirmed the long-held belief that respiratory and genitourinary infections are the most common causes of sepsis.

**PRINCIPLES OF DISEASE**

**Pathophysiology**

Sepsis is the endpoint of a complex process that begins with an infection. The initial host response is to mobilize inflammatory cells, particularly neutrophils and macrophages, to the site of infection. These inflammatory cells then release circu-
Definitions of Sepsis

**Bacteremia (fungemia):** presence of viable bacteria (fungi) in the blood, as evidenced by positive blood cultures.

**Systemic inflammatory response syndrome (SIRS):** at least two of the following conditions: (1) oral temperature of >38°C or <35°C, (2) respiratory rate of >20 breaths/min or partial pressure of arterial carbon dioxide (PaCO₂) of <32 mm Hg, (3) heart rate of >90 beats/min, (4) leukocyte count of >12,000/dL or <4000/dL or >10% bands.

**Sepsis:** SIRS that has a proven or suspected microbial source.

**Severe sepsis:** sepsis with one or more signs of organ dysfunction, hypoperfusion, or hypotension, such as metabolic acidosis, acute alteration in mental status, oliguria, or adult respiratory distress syndrome.

**Septic shock:** sepsis with hypotension that is unresponsive to fluid resuscitation plus organ dysfunction or perfusion abnormalities as listed for severe sepsis.

**Multiple organ dysfunction syndrome (MODS):** dysfunction of more than one organ, requiring intervention homeostasis.

---

Mediators of Sepsis

The nature of the body’s inflammatory response to a pathogenic insult is central to the pathophysiology of sepsis. The response is perhaps more important than the pathogen and is mostly responsible for determining patient outcome. A pathogen is sensed by pattern recognition receptors, most notably toll-like receptors, located on the surface of the white blood cell. The resulting host-pathogen interaction results in activation of the inflammatory and coagulation cascades.

The subsequent inflammatory signaling occurs via cytokines, chemokines, and other soluble mediators, including increased circulating levels of interleukin-1 (IL-1), IL-6, IL-8, and tumor necrosis factor alpha (TNF-α). Activation of the clotting cascade results in increased D-dimer levels (~100% patients) and decreased circulating levels of protein C (>90% patients). In benign conditions, a self-limited response helps to clear the pathogen. However, in more severe disease, unchecked proinflammatory and procoagulant activity leads to disruption of homeostasis as organs are damaged and the oxygen supply to vital organs is reduced. If uncorrected, the process leads to cellular hypoxia, organ dysfunction, shock, and death.

The primary mediators are cytokines that are primarily proinflammatory, anti-inflammatory, or growth promoting. The molecular mechanisms by which they are regulated are not well understood. The initial cytokine, TNF-α, is found in serum approximately 90 minutes after the administration of endotoxin to healthy volunteers. IL-6 and IL-8 reach peak levels at approximately 120 minutes. The main proinflammatory cytokines are IL-1, TNF, and IL-8. The primary anti-inflammatory cytokines are IL-10, IL-6, transforming growth factor beta, soluble receptors to TNF, and IL-1 receptor antagonist (IL-1ra). If the resultant inflammatory response is adequate, the infection is controlled and cleared. If the response is deficient or excessive, however, a persistent and worsening cascade is produced, ultimately leading to shock, organ failure, and potentially death.

IL-1 and TNF have both been implicated as key mediators in the development of sepsis. Increasing levels of circulating IL-1 and TNF correlate with worsening clinical status. At high doses, both IL-1 and TNF are lethal. They act by stimulating granulocyte-colony stimulating factors and activating leukocytes. TNF is present first in the bloodstream, and it induces the formation of IL-1. Infusing either cytokine into an animal model creates a sepsis syndrome. Selective blockade of either cytokine protects against sepsis in animal models. Anti-inflammatory regulators are released in response to rising proinflammatory mediators. IL-1ra is found in increased levels in healthy volunteers injected with endotoxin and many patients with infection. IL-10 has a purely anti-inflammatory role. In experimental models, it has been shown to decrease mortality in the presence of endotoxemia.

Other noncytokine molecules have been implicated in sepsis. Metabolites of the arachidonic acid pathway are involved in peripheral vasodilation, vasocostriction, and leukocyte and platelet aggregation. Prostaglandins are responsible for fever. Elevated thrombocoxane A₂ levels are found in sepsis.Little is known about the actual mechanisms by which eicosanoids participate in sepsis.

Instability in vascular tone is becoming increasingly important in our understanding of the pathophysiology of sepsis. Vasopressin, also known as antidiuretic hormone, is a naturally occurring hormone that is essential for cardiovascular stability. It is produced as a prohormone in the hypothalamus. The hormone is stored in the pituitary gland and released in response to stressors such as pain, hypoxia, hypovolemia, and hyperosmolality. In severe sepsis, there is a brief rise in circulating vasopressin levels followed by a prolonged and severe suppression. This pattern of secretion is different from other forms of shock in which vasopressin levels remain elevated. Vasopressin has numerous physiologic effects, including vasocostriction of the systemic vasculature, osmoregulation, and maintenance of normovolemia.
Nitric oxide (NO) is a gas that has an important role in septic shock, regulating vascular tone by an indirect effect on smooth muscle cells. NO also contributes to platelet adhesion, insulin secretion, neurotransmission, tissue injury, and inflammation and cytotoxicity. Its half-life is quite short (6–10 seconds) and it easily diffuses into cells. Although its mechanisms of action are not well understood, it seems to be a key mediator of sepsis. Animal data show that nitric oxide synthase, the enzyme that produces NO, is up-regulated in cases of sepsis. Enhanced NO production is thought to contribute to the profound vasodilation found in patients in septic shock.

In the setting of ongoing inflammatory activation, the mediators of sepsis continue to be produced and the cascade perpetuates. Unless appropriately and rapidly controlled, the ultimate effect is a sequence of events starting with cellular dysfunction and ultimately leading to tissue damage, organ dysfunction, and death.

**Organ System Dysfunction**

The organ dysfunction that results from sepsis is central to the pathogenesis of the disease. A 3000-patient ED-based study demonstrated that organ dysfunction with septic shock portends increasingly worse outcomes. Patients with suspected infection alone had a mortality rate of 2.1%, while the presence of SIRS criteria and suspected infection had a mortality rate of only 1.3% (Fig. 136-2A). However, the mortality rate was 9% for those patients with severe sepsis (sepsis plus organ dysfunction) and 28% for those with septic shock. The risk of death from sepsis approximately doubles for each organ that fails. The mortality rate for patients with no organ dysfunctions was 1.0%, while rates for single organ dysfunction, two organ dysfunction, three organ dysfunction, and four or more organ dysfunctions were 6%, 13%, 26% and 53%, respectively (Fig. 136-2B).

**Neurologic**

Patients with sepsis often display neurologic impairment manifested by altered mental status and lethargy, commonly referred to as septic encephalopathy. The incidence has been reported between 10 and 70%. The mortality rate in patients with septic encephalopathy is higher than in septic patients without significant neurologic involvement. One prospective case series showed that a Glasgow Coma Scale score of less than 13 correlated with an increase in mortality rate from 20 to 50%. Although the pathophysiology has not been clearly defined, contributing factors include direct bacterial invasion, endotoxemia, altered cerebral perfusion or metabolism, metabolic derangements, multiorgan system failure, and iatrogenic injury. In addition, impaired renal or hepatic function in the absence of overt organ failure has been shown to correlate with encephalopathy.

**Cardiovascular**

Profound cardiovascular dysfunction is common with sepsis. The etiology of cardiovascular dysfunction and failure arise from both direct myocardial depression and distributive shock. Gram-negative, gram-positive, and killed organisms can cause myocardial depression. The direct insults of the toxic mediators as well as the mobilization of host mediators of sepsis produce a distributive shock. Early in sepsis, a hyperdynamic state develops, characterized by increased cardiac output and decreased systemic vascular resistance. Although the cardiac output is increased, it is at the expense of ventricular dilation and decreased ejection fraction. Aggressive fluid resuscitation usually increases preload and, secondarily, ejection fraction, thereby improving the cardiac index, even late in shock. Much of the cardiovascular compromise from septic shock is reversible, and normal cardiovascular function usually returns within 10 days.

**Pulmonary**

The lung is an early victim to the inflammatory response to sepsis. These effects are apparent irrespective of the primary infection that caused sepsis. Early infiltration with neutrophils, surfactant dysfunction, and edema later give way to monocyte infiltration and fibrosis. Significant right-to-left shunting, arterial hypoxemia, and intractable hypoxemia occur. The resulting morbidity is high and is a common endpoint to sepsis-related deaths.

Sepsis produces a highly catabolic state and places significant demands on the respiratory system. At the same time, airway resistance is increased and muscle function is impaired. Irrespective of whether pneumonia is the cause of sepsis, the common pulmonary endpoint is acute respiratory distress syndrome (ARDS). ARDS is defined clinically and correlates with the pathologic finding of diffuse alveolar damage. The development of ARDS occurs 4 to 24 hours after radiographic abnormalities develop. Because of alveolar-capillary membrane damage, fluid accumulates in the alveoli. Rather than being a diffuse disease, ARDS is a heterogeneous process that results in interspersed damaged and normal alveoli.
Impaired oxygenation, defined as a ratio of partial pressure of arterial oxygen to fractional inspired oxygen <200, irrespective of how much positive end-expiratory pressure is used

Bilateral pulmonary infiltrates on frontal chest radiograph
Pulmonary artery occlusion pressure ≤18 mm Hg or no clinical evidence of elevated left atrial pressures

**Gastrointestinal**

The hollow viscus is significantly affected by the shock state. A prolonged ileus accompanies hypoperfusion and persists beyond the malperfused state. Splanchnic blood flow is dependent on mean arterial pressure because there is relatively little autoregulation. Therefore, hemodynamic dysfunction may have a profound effect on viscus metabolism.

Solid organ involvement is also common. Even in the previously normal host, elevations in aminotransferases and bilirubin are common early in sepsis, although frank hepatic failure is quite rare. The liver has also been implicated in the pathogenesis of sepsis; some of the mediators of sepsis are produced by the liver.

**Endocrine**

The presence of an absolute or relative adrenal insufficiency is common in sepsis. Depending on the balance of circulating cytokines, augmentation or suppression of the hypothalamic-pituitary axis is possible. IL-1 and IL-6 both activate the hypothalamic-pituitary-adrenal axis. TNF-α and corticostatin depress pituitary function. Other factors that may contribute to adrenal insufficiency in sepsis include decreased blood flow to the adrenal cortex, decreased pituitary function, and decreased pituitary secretion of adrenocorticotropic hormone due to severe stress. As a result of these interactions, the hypothalamic thermoregulatory mechanism may be reset, and temperature lability may develop.

**Hematologic**

Sepsis causes abnormalities in many parts of the coagulation system. Endotoxin, TNF-α, and IL-1 are the key mediators. Pathologic activation of the extrinsic (tissue factor–dependent) pathway, protein C–protein S, and fibrinolysis lead to consumption of essential factors, causing disseminated intravascular coagulation (DIC). The activation of the coagulation cascade produces fibrin deposition and microvascular thrombi. If not corrected, these depositions can compromise organ perfusion and contribute to organ failure. Tissue factor expression on monocytes is increased. This results in fibrin deposition and perhaps contributes to an increased incidence of multorgan failure due to microvascular thrombi. In one study, the degree of tissue factor expression was found to portend a poorer prognosis.

Protein C has been identified as an important modulator of both inflammation and coagulation in patients with sepsis. Impairment of the protein C–dependent anticoagulation pathway is critical to the development of the thrombotic complications of sepsis. In healthy humans, protein C is activated by a combination of thrombin and thrombomodulin. The activation of protein C results in down-regulation of many portions of the coagulation cascade, including release of tissue factor, inactivation of factor VIIIa and factor Va, and stimulation of fibrinolysis. It is possible that protein C activation in early sepsis is impaired because of an inflammatory cytokine-mediated down-regulation of thrombomodulin. As a result, a consumptive coagulopathy ensues. This leads to increased fibrin deposition and a resulting up-regulation of the fibrinolytic pathway as identified by low plasma levels of the fibrinolytic proteins and increased fibrin-split products. This sequence of events leads to consumption of coagulation factors and DIC. In late sepsis, the fibrinolytic system is suppressed.

**CLINICAL FEATURES**

**Symptoms and Signs**

The approach to a patient with sepsis relies on identifying the presence of a systemic infection, as well as localizing the source of the initial infection. This allows for appropriate and aggressive directed treatment to the source of sepsis. Often, the source is not readily apparent, but early identification of the septic state allows implementation of broad-spectrum antibiotics that may be potentially lifesaving.

Patients with altered consciousness who are unable to protect their airway require intubation. Septic patients with severe tachycardia or hypoxia with impending respiratory failure also require intubation to allow positive pressure ventilation. Patients needing hemodynamic blood pressure support must be identified and rapidly and aggressively treated with fluids and vasopressor and inotropic support as needed.

The septic patient manifests signs of systemic infection through tachycardia, tachypnea, hyperthermia or hypothermia, and, if severe, hypotension. A septic patient will often have flushed skin with warm, well-perfused extremities secondary to the early vasodilation and hyperdynamic state. Alternatively, the severely hypoperfused patient with an advanced shock state may appear mottled and cyanotic. Very early in the patient’s presentation, vital sign changes such as tachycardia and tachypnea may be the only early indicators of sepsis.

If the patient is in shock, a rapid assessment that excludes other causes, such as hypovolemic or cardiogenic shock, is essential to the proper initial treatment. A complete detailed clinical examination will help the physician determine the cause of the shock state (see Chapter 4). The aforementioned are “classic” signs; a septic patient may not manifest these findings, and signs and symptoms may be subtle. In evaluating the patient with septic shock, the cause must be considered: sepsis is a pathogenic insult resulting in a dysregulated inflammatory cascade with release of proinflammatory and anti-inflammatory mediators.

Both underlying comorbidities and the etiology of sepsis should be considered. In the evaluation of the septic patient, Risk factors, such as immunocompromised states (acquired immunodeficiency syndrome, malignancy, diabetes, splenectomy, and concurrent chemotherapy), older age, debilitation or high-risk environments for iatrogenic infections (such as long-term care facilities), and multiple comorbidities should be considered.

The respiratory system is the most common source of infection in the septic patient. A history of a productive cough, fevers, chills, upper respiratory symptoms, and throat and ear pain should be sought. Both the presence of pneumonia and the findings of tachypnea or hypoxia have been found to be predictors of death in patients with sepsis. Physical examination should also include detailed evaluation for focal infection,
such as exudative tonsillitis, sinus tenderness, tympanic membrane injection, and crinkles or dullness on lung auscultation. Also, pharyngeal thrush should be noticed as a potential marker of an immunocompromised state.

The gastrointestinal system is the second most common source of sepsis. A history of abdominal pain, including its description, location, timing, and modifying factors should be sought. Further history, including the time of the last bowel movement and the presence of nausea, vomiting, and diarrhea, should be noted. A careful physical examination, looking for signs of peritoneal irritation, abdominal tenderness, and hyperactive or hypoactive bowel sounds, is critical in identifying the source of abdominal sepsis. Particular attention must be paid to physical findings suggestive of common sources of infection or disease: Murphy’s sign indicating cholecystitis, pain at McBurney’s point indicating appendicitis, left lower quadrant pain suggesting diverticulitis, or rectal examination revealing a rectal abscess or prostatitis.

The neurologic system is examined by looking for signs of meningitis, including nuchal rigidity, fevers, and change in consciousness. A detailed neurologic examination is important. Lethargy or altered mentation may indicate primary neurologic disease or may be the result of decreased brain perfusion from a shock state.

The genitourinary history includes queries regarding the presence of flank pain, dysuria, polyuria, discharge, Foley catheter placement, and genitourinary instrumentation. A sexual history should assess for the risk of sexually transmitted diseases. Genitalia should be evaluated for ulcers, discharge, and penile or vulvar lesions, looking specifically for the woody induration of Fournier’s gangrene. A rectal examination should be performed, looking for a tender, boggy prostate, consistent with prostatitis. A red and friable cervix, vaginal discharge, or cervical motion tenderness is consistent with a sexually transmitted disease. Adnexal tenderness in a toxic-appearing female potentially represents a tubo-ovarian abscess.

Musculoskeletal history includes the presence of any localizing symptoms to a particular joint. Redness, swelling, and warmth over a joint, especially if there is a decreased range of motion in that joint, may be signs of septic arthritis and may mandate arthrocentesis. A patient should be completely exposed and the skin examined for evidence of cellulitis, abscess, wound infection, or traumatic injury. Deep injuries, foreign bodies, and fasciitis may be difficult to identify clinically. The physician should look for crepitus representing the presence of an aggressive, gas-forming organism. Local lymphadenopathy, swelling, and streaking should also be noted as signs of an advancing infection. Petechiae and purpura may represent a Neisseria meningitidis infection or DIC. Generalized erythroderma and rash may represent an exotoxin from pathogens such as Staphylococcus aureus or Streptococcus pyogenes.

A history of fevers or chills in the setting of intravenous drug abuse, an artificial heart valve, or mitral valve prolapse should increase the suspicion of endocarditis. The clinician should suspect endocarditis in the presence of a murmur or other stigmata of endocarditis (e.g., splinter hemorrhages, Roth’s spots, Janeway lesions).

Clinicians must identify the severity of illness in patients with infection and initiate aggressive resuscitation for those patients with the potential of becoming critically ill. Although a patient may meet SIRS criteria, this alone has little predictive value in determining the severity of illness and mortality.60 The Mortality in Emergency Department Sepsis (MEDS) score is a method to risk stratify ED patients with sepsis.82 The MEDS prediction rule assigns point values to specific clinical characteristics (Table 136-1). The total score can be used to assess risk of death. Thus, the greater the number of risk factors, the more likely a patient is to die during the hospitalization.

### Diagnostic Strategies

The use of diagnostic testing in patients with sepsis syndromes or suspected syndromes serves two purposes. Diagnostic studies are used both to identify the type and location of the infecting organisms and to define the extent and severity of the infection to assist in focusing therapy. As a result, the diagnostic approach must be tailored to the particular patient.

### Hematology

The white blood cell count is a marker of inflammation and activation of the inflammatory cascade. Leukocytosis is associated with infection and is incorporated in the consensus definition of sepsis; however, it is often insensitive and nonspecific, limiting its absolute utility in the ED. The febrile neutropenic patient has been shown to be at increased risk for severe infection. Thus, a white blood cell count of less than 500 cells/mm³ should prompt admission, isolation, and empirical intravenous antibiotics in most chemotherapy patients. A bandemia (>10% bands on a peripheral smear) represents the release of immature cells from the bone marrow and is considered to be a sign of infection and inflammation. Like the white blood cell count, it is an imperfect indicator of infection. The absence of leukocytosis or bandemia does not preclude the possibility of severe sepsis, nor does their absence have any proven predictive value in determining mortality risk. The hemoglobin and hematocrit should be obtained to ensure adequate oxygen delivery in shock. Patients should be maintained with a hematocrit greater than 30% and hemoglobin greater than 10 g/dL. Platelets are an acute-phase reactant and may be elevated in the presence of infections. Conversely, a low platelet count has been found to be a significant predictor of bacteremia in patients with shock.81,83,84 Thrombocytopenia, elevated pro-

thrombin time, an elevated activated partial thromboplastin time, decreased fibrinogen, and increased fibrin split products are associated with DIC and severe sepsis syndrome.

Chemistry

Electrolyte abnormalities should be identified and corrected. Low bicarbonate level suggests acidosis and inadequate perfusion. An elevated anion gap acidosis in the setting of sepsis syndrome commonly represents lactic acidosis or diabetic ketoacidosis, but other causes need to be ruled out. Elevated serum creatinine or decreased glomerular filtration rate is indicative of renal dysfunction or failure, which, if due primarily to sepsis, indicates organ failure and a worse prognosis. Calcium, magnesium, and phosphorus levels should be checked.

The presence of an elevated lactate level is associated with inadequate perfusion, shock, and a poorer prognosis.85 One ED-based study showed a progression in mortality rate with increasing venous lactate level: a lactate level of 0 to 2.5 mg/dL was associated with a 5% mortality rate; a lactate level of 2.5 to 4.0 mg/dL, 9% mortality; and greater than 4 mg/dL, 28% mortality.85 An arterial blood gas assessment may be helpful in identifying and classifying acid-base disturbances. Metabolic acidosis suggests inadequate tissue perfusion. Liver function tests can be used to identify liver failure or dysfunction. An elevated bilirubin level may suggest the gallbladder as a cause of sepsis. An elevated amylase and lipase level may represent pancreatitis as the cause of noninfectious SIRS.

Microbiology

Obtaining proper blood, sputum, urine, cerebrospinal fluid, and other tissue culture samples is important in guiding therapy. Although not helpful in the initial management, culture samples should be obtained before or soon after the administration of antibiotics in the patient with sepsis syndrome. The initiation of antibiotic therapy should not be delayed while waiting for culture samples to be obtained. One well-designed prospective study suggests the following factors as predictive of a positive blood culture: fever greater than 38.3°C, the presence of a rapidly (<1 month) or ultimately (<5 years) fatal disease, shaking chills, intravenous drug abuse, acute abdomen, or major comorbidity. These factors have not been validated in independent populations. The literature suggests that the yield of initial blood cultures is low (5–10%), but this is likely an artifact of the lack of reliable discriminatory guidelines for obtaining blood culture samples in the ED. Among patients with clinical sepsis, only 30 to 60% of patients will have positive cultures.5,6,15

The results of initial microbiologic tests, including Gram’s stains whenever possible, will help guide subsequent antibiotic treatment, but initial empirical therapy should be broad spectrum to allow for early treatment of all likely organisms.

Special Procedures

The comprehensive protocol of early goal-directed therapy published by Rivers and associates86 showed that a resuscitation strategy guided by central venous pressure (CVP), an arterial line, and a central venous catheter with continuous central venous oxygen saturation (ScvO2) monitoring capability can reduce mortality in patients with sepsis. However, whether each of these components is mandatory is unclear. A CVP line may guide fluid resuscitation, with a low CVP indicating the need for continued fluid repletion. The goal CVP is 8 to 12 mm Hg in patients not on mechanical ventilation, and 12 to 16 mm Hg in patients who are ventilated. The ScvO2 monitor measures venous blood saturation, which is a marker of tissue metabolism and extraction. It has been suggested that intermittent monitoring of ScvO2 may suffice, although there are no firm data to support this. The goal is to ensure proper tissue oxygenation, which is routinely achieved by adjusting oxygen delivery, keeping the ScvO2 greater than 70%. An arterial line can be useful for close monitoring of hypotensive patients, especially when one or more vaspressors are being titrated to maintain an adequate blood pressure; however, it is not necessarily mandatory. Finally, the Swan-Ganz catheter is not a mandatory part of the ED management, although the physiologic measurements may be useful in identifying the cause of shock and guiding fluid and inotropic therapy. Low systemic vascular resistance and high cardiac output are most commonly associated with sepsis, although this may vary with the stage of shock and the individual patient. There is literature that indicates the use of Swan-Ganz catheters does not substantially impact mortality.89

Radiology

A chest radiograph should be obtained in all patients with suspected sepsis syndrome, looking not only for a focal infiltrate representing pneumonia but also for the fluffy, bilateral infiltrates indicative of ARDS. The pathophysiology of ARDS is often delayed as much as 24 hours after radiographic identification. An upright chest radiograph should be obtained for suspected bowel perforation to detect free air under the diaphragm. The presence of pneumomediastinum is suggestive of esophageal perforation and current or impending mediastinitis.

Soft tissue plain radiographs of infected areas should be obtained, looking for air in the soft tissues associated with necrotizing or gas-forming infection. Periosteal thickening or bone erosion may be seen on plain radiographs of patients with osteomyelitis; a bone scan may be diagnostic. Computed tomography (CT) of superficial infections may be helpful to further quantify the extent of infection and to identify abscesses that are not readily evident on physical examination. A CT scan of the abdomen and pelvis may identify abdominal or pelvic pathologic lesions, provided there is no clear clinical indication for immediate operative intervention. Suspected diseases such as diverticulitis, appendicitis, necrotizing pancreatitis, microperforation of the stomach or bowel, or formation of an intra-abdominal abscess may be best diagnosed by CT scan. A head CT scan can identify septic emboli from endocarditis or increased intracranial pressure from a mass and should be considered before a lumbar puncture is performed. An abdominal ultrasonogram may be indicated for suspected cholecystitis, and a pelvic ultrasonogram for tubo-ovarian abscess or endometritis. A transesophageal echogram should be obtained if endocarditis is suspected to detect the presence of any valvular vegetations. A magnetic resonance imaging scan can be useful to identify soft tissue infections such as necrotizing fasciitis or epidural abscess.

DIFFERENTIAL CONSIDERATIONS

The sepsis syndromes represent a spectrum of disease and clinical presentation. SIRS is defined by hemodynamic and laboratory parameters alone, whereas sepsis must include a suspected infectious cause. Often, noninfectious sources can cause a syndrome that mimics sepsis; thus, one must keep in mind a broad differential diagnosis when approaching these patients (Box 136-3). A detailed history and physical examination are always the first step in narrowing the differential diagnosis to identify the true source.

- Paralysis

MANAGEMENT

Early detection and aggressive management can significantly reduce the chance of mortality from sepsis. Antimicrobial therapy and maintenance of adequate tissue oxygenation and perfusion remains the primary goal, but the means by which this is achieved has changed substantially in the past years. With the advent of early goal-directed therapy and therapies such as drotrecogin alfa targeting the cascade leading to septic shock, there is increasing evidence that the natural history of sepsis can be altered. Initial resuscitation, including appropriate airway management, intravenous access, oxygen, early and appropriate antibiotics, and fluid resuscitation remain the foundation on which new efforts may be applied.

In the study by Rivers and associates, a protocol for early and aggressive care was used to guide resuscitation in the ED. This randomized, double-blind, placebo-controlled study showed a 16% mortality reduction in patients with severe sepsis and septic shock. The protocol measures targeted “goals” and uses a resuscitation algorithm to facilitate an aggressive and early resuscitation. The use of this strategy has been endorsed by the Surviving Sepsis Campaign, an international consensus panel. The recommendation is for the use of goal-directed therapy on all patients who have: (1) suspected infection, (2) two or more SIRS criteria, and (3) evidence of hypoperfusion signified by either a systolic blood pressure of less than 90 mm Hg after 20 to 30 mL/kg fluid challenge or a lactic acid level greater than 4 mmol/L. (Fig. 136-3). The theory behind the protocol is to normalize preload and pressure and to prevent tissue hypoxia by matching oxygen delivery with consumption.

1) Supplemental oxygen +/- intubation
2) Central venous line placement with continuous ScvO2 capability
- Central venous pressure 8–12
- Mean arterial pressure <65 or >90
- ScvO2 < 70%
- Transfuse – Hct >30%
- Dobutamine

Figure 136-3. Summary of goal-directed therapy protocol.

Preload

The first step in goal-directed therapy is to provide a proper filling pressure to ensure adequate cardiac preload. Patients in sepsis and septic shock are often in a state of substantial fluid deficit. Rivers and colleagues showed that patients required an average of 5 L of fluids in the first 6 hours of their resuscitation. A CVP measurement should be obtained, and the patients should receive crystalloid or colloid resuscitation to keep the CVP at a level of 8 to 12 mm Hg. In intubated patients with positive pressure ventilation, pathophysiologic principles support raising the target level to 12 to 16 mm Hg.

Perfusion Pressure

The next step in goal-directed therapy is to maintain an adequate blood pressure. A mean arterial blood pressure (MAP) should be kept between 60 and 90 mm Hg. If the mean arterial blood pressure is below 65 mm Hg in the presence of adequate preload, treatment with a vasopressor agent should be started, with norepinephrine or dopamine being considered first-line agents.

Oxygen Delivery

The initial management of all critically ill patients should include adequate supplemental oxygen to provide adequate peripheral oxygen saturation. In the adult patient, continuous peripheral oxygen saturation monitoring should be implemented and supplemental oxygen should be provided to maintain a saturation of 95% or the patient’s baseline in the case of underlying lung disease. Once preload and pressure are normalized, the next focus is on oxygen delivery. A mixed venous saturation assessment can be used to guide this part of the resuscitation. Organ hypoperfusion is a result of global and distributive changes in both systemic blood flow and the microvasculature. As a result of marrow suppression and dilution with crystalloid fluids, many patients with sepsis have a hemoglobin between 8 and 10 g/dL after initial resuscitation. A hematocrit between 27 and 30% has been reported to be most effective, although other studies challenge this dogma.

The goal is to maintain a mixed venous saturation (ScvO2) greater than 70%. As oxygen demand due to sepsis increases, the ScvO2 starts to fall below 70%. This must be corrected by first ensuring that preload and pressure are adequate. Next, the arterial oxygen saturation should be optimized with non-rebreather oxygen delivery or intubation, as needed. Once these targets are optimized, one should ensure that the patient has...
adequate oxygen-carrying capacity by transfusing the patient to a hematocrit greater than 30%. If this is normalized, and the patient is not tachycardic, dobutamine can be added to increase cardiac contractility and increase cardiac output, resulting in an overall improved oxygen delivery. The protocol should be run continuously with an effort toward normalizing the parameters during the entire resuscitation (Table 136-2).

Respiratory Support

Altered mental status is common in patients in septic shock, and they may require rapid airway protection. Patients with a respiratory rate greater than 30 breaths per minute are likely to develop respiratory collapse, irrespective of arterial oxygenation. Wheeler and coworkers\(^7\) reported that 85% of patients with “severe sepsis” require mechanical ventilation during their hospital course. Because patients with impending respiratory failure use a disproportionately large amount of energy for the muscles of respiration, improved oxygen delivery to other organs is achieved by mechanical ventilation, sedation, and paralysis. Although there are no clear intubation guide-

Cardiovascular Support

Fluid Resuscitation

Patients with sepsis often require large volumes of intravenous fluid to maintain adequate perfusion.\(^7\) The primary reasons for this intravascular hypovolemia are venodilation and diffuse capillary leak.\(^7\) Initial therapy for adults with septic shock should generally be 2 L of isotonic crystalloid. As much as 6 to 10 L of crystalloid may be required in the first 24 hours.\(^7\) Early goal-directed therapy has been shown to be an effective way to guide fluid resuscitation and should be considered in all cases of septic shock. In less critically ill patients, fluid replacement should be titrated to clinical parameters such as heart rate, blood pressure, change in mental status, capillary refill, cool skin, and adequate urine output (0.5–1 mL/kg/hr). Normal (0.9%) saline and Ringer’s lactate solution are equally effective and neither worsens lactic acidosis. Colloids are as effective as crystalloids, but they are far more expensive. Experience with hypertonic saline is limited, and no recommendation on its use can be made based on current literature.\(^7\) There have been recent efforts to identify ways to measure regional perfusion more directly. In particular, direct measurement of splanchnic blood flow has been proposed. Even in the absence of global hypoxia and impaired tissue perfusion, there is evidence that regional hyperperfusion and ischemia exist.\(^7\) Although further study is necessary, there is early evidence that therapy guided toward maintaining splanchic perfusion can decrease the rate of mortality.\(^7\)

Vasopressors

If appropriate fluid resuscitation has failed, vasopressor support may be required (Table 136-3). Only in cases of profound hypotension should vasopressors be started before adequate fluid resuscitation. Using mean arterial pressure alone as an

Epinephrine

Epinephrine a very potent mixed alpha and beta agonist. Epinephrine infusion is also associated with increased oxygen consumption, increased systemic lactate concentrations, and decreased splanchnic blood flow. Studies have shown that the rise in lactate is short-term and there is no evidence regarding the long-term effects. As a result of all of the possible adverse effects of epinephrine, it is currently recommended only for those patients who are unresponsive to other vasopressors.

Vasopressin

Vasopressin is a naturally occurring nonapeptide that is synthesized as a large prohormone in the hypothalamus. In states of septic shock, there is an early surge of vasopressin followed by a profound drop in circulating vasopressin levels. This is the foundation for using vasopressin as an adjunct therapy for patients with severe sepsis. Vasopressin should not be used as the sole initial therapy for refractory septic shock. In a well-designed randomized trial, investigators demonstrated no change in mortality for patients with severe sepsis when vasopressin was added to catecholamine vasopressors.

Inotropic Agents

Dobutamine

Dobutamine is a mixed alpha- and beta-agonist. In dosage ranges from 2 to 28 µg/kg/min, cardiac index is increased at the expense of heart rate. In addition, decreased splanchnic blood flow is common. Its use should be reserved for patients with depressed cardiac index and persistent hypoperfusion in spite of adequate volume expansion and other vasopressor agents. In patients undergoing formal early goal-directed therapy, when preload, perfusion pressure, and oxygen-carrying capacity have been normalized, and a low ScvO₂ persists, dobutamine is used to increase cardiac output and oxygen delivery.

Bicarbonate

Bicarbonate supplementation was previously the standard of care for patients with presumed lactic acidosis. Current consensus is that it should be reserved for severe acidemia (pH < 7.0–7.2), as there may be a paradoxical decrease in intracellular pH as a result of diffusion of soluble CO₂ across the cell membrane. Alternatively, hyperventilation has been suggested to help increase systemic pH.

Antibiotics

Early and appropriate antibiotic therapy should target the nidus of infection; this reduces mortality, perhaps by as much as 30 to 50%. If the patient’s condition permits, appropriate cultures should be drawn before the administration of broad-spectrum antibiotics (Table 136-4). Surgically correctable conditions, such as intra-abdominal abscesses, perforated viscus, retained products of conception, or retained foreign body (such as a tampon), should be treated concurrently.

In the absence of an obvious source of infection, the use of broad-spectrum antibiotics is recommended. The specific agent depends on many variables, including institutional preference and local resistance patterns. As results from cultures become available, therapy should be modified. There is no consensus about the need for double or triple antibiotic coverage for particular organisms, although it is common practice to double-cover virulent organisms, such as P. aeruginosa, as well as areas that are commonly infected with multiple organisms such as the peritoneum. And, with increasing rates of methicillin-resistant organisms, combinations that include nonpenicillin choices may be warranted.

**Novel Therapies**

**Activated Protein C**

After years of unsuccessful, large-scale, multicenter trials of novel therapeutic agents for sepsis, recombinant activated protein C (APC) became the first therapy to be approved by the Food and Drug Administration (FDA) for the treatment of sepsis. APC was shown to improve survival by 6.1% in patients with severe sepsis. This benefit is realized most in patients who are more severely ill, as characterized by an APACHE II score greater than 25. The FDA has approved APC for use in this group only. A recent cost-benefit analysis estimated the cost per life-year saved by APC to be $27,936 in all patients. When stratified by severity of illness, the cost-benefit in patients with an APACHE II score less than 25 is $24,484 per life-year saved; for those with an APACHE II score greater than 25, it is $575,054 per life-year saved. Although its use primarily occurs in the intensive care unit, patient selection can begin in the ED. Additionally, an emphasis continues to be placed on early intervention in the appropriate patient to enhance its benefit. However, recent negative trials in a lower-risk adult population and a pediatric population both raise some doubts about the efficacy of the medication and emphasize the need to optimize the risk:benefit ratio by targeting more critically ill patients who are likely to receive the most benefit from therapy.

**Steroid Therapy**

It has been nearly 30 years since the first treatment attempts to block inflammation in sepsis. Because sepsis involves a systemic inflammatory response, corticosteroids are a logical treatment modality as anti-inflammatory agents. Physicians have been working for decades to prove or disprove their value. A large study in the mid-1980s conducted by the Veterans Administration Systemic Sepsis Cooperative Study Group found no reduction in mortality among patients receiving early methylprednisolone therapy. Bone and associates also studied the use of methylprednisolone in patients with sepsis and found increased mortality in those patients who were randomized to the steroid arm. Briegel and associates showed decreased time of vasopressor therapy with stress doses of hydrocortisone but no reduction in mortality. Annane and associates performed a randomized, double-blind, placebo-controlled study of 300 patients with septic shock that demonstrated benefit when steroids (hydrocortisone, 50 mg IV every 6 hours, plus fludrocortisone, 50 µg each
day) were given to nonresponders in a corticotropin stimulation test. Among nonresponders, those treated with steroids had a 53% mortality rate, compared to 63% in the placebo group, for a 10% absolute benefit. Steroid therapy was not beneficial to those who responded to the corticotropin stimulation test. Marik and Zaloga\(^1\) asserted that an initial random cortisol level of less than 25 µg/dL should be used to determine adrenal insufficiency. However, a recent large-scale multicenter validation failed to show a statistically significant improvement in mortality in both all-comers with septic shock as well as those with adrenal suppression.\(^1\) Steroids were more effective in reducing the amount of time patients spent hypotensive, but the rates of secondary infection increased, contributing to a null effect overall. At this time, with somewhat conflicting data, the utility of steroids in sepsis remains controversial and should be reserved for cases where the risk of cardiovascular collapse from refractory hypotension due to adrenal suppression outweighs the risk of increased morbidity and mortality from secondary infection.

**Disposition**

Once the ED management is complete, antibiotics are given, and the need for emergency operative intervention or procedure has been excluded, patients who are deemed at increased risk should be admitted to the hospital. Patients with septic shock should be admitted to an intensive care unit, and those with one of the other sepsis syndromes can be admitted to a monitored floor with close supervision or an intensive care unit, as needed.

### Key Concepts

- **Sepsis** is a progression of disease due to a dysregulated inflammatory cascade, leading to organ dysfunction and circulatory compromise in severe cases.
- **Elders**, immunocompromised and neutropenic patients, and patients with multiple comorbidities are at increased risk for development of sepsis syndromes.
- Early goal-directed therapy can improve the outcome of patients with sepsis. Treatment should focus on (1) improving tissue perfusion (through administration of fluids and vasopressor medications), (2) improving tissue oxygenation (through administration of oxygen and positive pressure ventilation), (3) administration of appropriate antibiotics, and (4) early identification of infections requiring surgical management.

Environment and Toxicology
Peripheral cold injuries occur primarily in humans. The highest homeostatic priority is to maintain the body’s core temperature. This is accomplished through vasoconstriction and shunting, which prevents adequate heat distribution to the extremities. As a result, failure to achieve adequate protection from the environment results in injuries that are usually preventable.1–4 Peripheral cold injuries include both freezing and nonfreezing syndromes, which may occur independently or in conjunction with systemic hypothermia.5 Frostbite is the most common freezing injury.6 Trench foot and immersion foot are nonfreezing injuries that result from exposure to wet cold.7 Nonfreezing injury that usually occurs after exposure to dry cold is termed chilblains (pennio). The incidence and severity of frostbite correlate with the predisposing factors associated with the cold stress. Most cases of civilian frostbite result from routine exposure to cold by individuals who have not given due consideration to risk factors for cold injury.8–10 Well-equipped treks up the world’s highest peaks have been completed without cold injury when appropriate steps are taken to address these factors.11 Current trends show an increase in outdoor recreational activities that produce exposure to unanticipated drastic climatic changes.12,13 Unsheltered and homeless people are no longer the most likely group at risk.

Military history is replete with accounts of the effects of cold injury on combat troops.14,15 Amputations and time lost to local cold injuries in both World Wars and the Korean conflict were extensive. Trench foot was particularly common among the Royal Marines in the Falkland Islands and United States troops in the Vietnam War.

Napoleon’s Surgeon General, Baron de Larrey, first recorded the disastrous effects of the freeze-thaw-refreeze cycle.16 During the 1812 to 1813 Russian invasion and retreat, soldiers would acutely thaw frozen extremities directly over open fires. The subsequent refreeze further increased tissue destruction. Unfortunately, the resultant gangrene was misattributed to this rapid thawing of frostbite and trench foot injuries. Therefore, gradual thawing, often including friction massage with snow, remained the standard treatment regimen until the 1950s.17,18 In addition to dry radiant heat rewarming and massage, another misdirected rewarming modality was immersion thawing in icy water. In 1961, Mills ultimately popularized rapid warm immersion rewarming after extensive experience with severe Alaskan frostbite cases.18,19

Physiology

Human cold stress should induce adaptive behavioral reactions such as an attempt to find heat or shelter. In addition, complex endocrinologic and cardiovascular physiologic responses are engaged. Peripheral cooling of the blood activates the preoptic anterior hypothalamus. This central thermostat orchestrates temperature regulation. This dynamic process encompasses catecholamine release, thyroid stimulation, shivering thermogenesis, and peripheral vasoconstriction.

Cutaneous circulation is one of the keys to maintaining thermoneutrality. Baseline cutaneous circulation greatly exceeds the nutritional requirements. This reflects the skin’s “radiator” function to maintain thermostat. Cutaneous blood flow in the euthermic 70-kg human averages 200 to 250 mL/min. Heat stress causes vasodilation that can increase this amount to 7000 mL/min. In contrast, extreme cold-induced vasoconstriction reduces flow 10-fold to less than 50 mL/min.

During cold stress, peripheral vasoconstriction limits radiant heat loss. Acral skin structures (fingers, toes, ears, nose) contain a plethora of arteriovenous anastomoses. These facilitate shunting and subsequent drastic reductions in blood flow to these areas. This “life-versus-limb” mechanism reflects the homeostatic attempt to prevent systemic hypothermia.

In contrast to heat exposure, humans do not appear to display significant physiologic adaptation to the cold. Exposing extremities to temperatures down to 15° C results in maximal peripheral vasoconstriction with minimal blood flow. Continued exposure to progressively colder temperatures down to 10° C produces the “hunting response,” which is termed cold-induced vasodilation.20 These periods of vasodilation, recurring in 5- to 10-minute cycles, interrupt vasoconstriction and serve to protect the extremity. Eskimos, as well as Lapps and others of Nordic extraction, are capable of stronger cold-induced vasodilation than individuals from tropical regions. Measuring the speed of cold-induced vasodilation may help predict an individual’s risk for cold injury.21

Pathophysiology

The pathologic phases that occur with local cold injury often overlap and vary with the extent and rapidity of the cold response (Box 137-1). Frostbite occurs when the tissue temperature drops to less than 0° C. There are two putative
An additional insult, progressive dermal ischemia, is partially mediated by thromboxane. Fluid analysis of clear vesicles identifies prostaglandins. When subdermal vascularplexes are injured, hemorrhagic blisters develop that also contain these prostaglandins. The arachidonic acid breakdown products released from underlying damaged tissue into the blister fluid include both prostaglandins and thromboxane. These mediators produce platelet aggregation, vasoconstriction, and leukocyte immobilization.

The ultimate determinant of progressive tissue damage appears to be injury to the microvasculature. Endothelial cells are the tissue most susceptible to freezing injury. After thawing, the vasculature is patent only temporarily. Platelet and erythrocyte aggregates promptly clog and distort the vasculature. Intense vasoconstriction coupled with arteriovenous shunting occurs at the interface between normal and damaged tissue. The injured viable vasculature remains distorted. Local arteritis, medial degeneration, and intimal proliferative thickening are seen. Nerve and muscle tissues are also more susceptible to cold injury than connective tissue. For example, nonviable hands and feet can be moved after thawing if the tendons are intact.

Edema progresses for 48 to 72 hours after tissue has been thawed. Leukocyte infiltration, thrombosis, and early necrosis become apparent as this edema resolves. The dry gangrene carapace of frostbite is superficial in comparison to arteriosclerotic-induced, full-thickness gangrene. Final clinical demarcation between viable and nonviable tissue can require more than 60 to 90 days, hence the historical surgical aphorism, “Frostbite in January, amputate in July.” Advances in imaging modalities can accelerate the identification of demarcation.

### Predisposing Factors

The extent of peripheral cold injury is determined by the type and duration of cold contact with the skin. Any conditions affecting judgment can jeopardize the physiologically tropical human. In urban settings, cold injuries are often attributed to overt or covert risk taking or psychiatric impairment or ingestion of intoxicants. Ethanol also produces peripheral vasodilation, which increases heat loss. Whenever self-protective instincts are blunted, appropriate adaptive maneuvers may not be undertaken.

Direct skin contact with good thermal conductors such as metal, water, and volatile liquids affects the extent and rapidity of tissue destruction. Commercial aerosol spray propellants such as propane and butane are potentially hazardous. One passenger on a commercial airline flight suffered a full-thickness lumbar injury from a “cold pack” provided by the stewardess that contained dry ice. Overenthusiastic application of standard ice packs while treating soft tissue injuries can also result in tissue loss. Although air alone is a poor thermal conductor, associated cold and wind (wind chill index) markedly increase heat loss.

### CLINICAL FEATURES

#### Symptoms and Signs

“Frostnip” is a superficial cold insult manifested by transient numbness and tingling that resolves after rewarming. This does not represent true frostbite, because no tissue destruction occurs.

The symptoms of frostbite usually reflect the severity of the exposure. The most common presenting symptom is numbness, present in more than 75% of patients. All patients...
have some initial sensory deficiency in light touch, pain, or temperature. Anesthesia is produced by intense vasoconstrictive ischemia and neurapraxia. Acral areas and distal extremities are the usual insensate sites. The distal extremities—the fingers, toes, nose, ears, and penis—are specific locations at risk. Patients often complain of clumsiness and report a “chunk of wood” sensation in the extremity. The history of complete acute anesthesia in a painful cold digit suggests a severe injury.

Significant pain usually accompanies reestablishment of perfusion. With partial tissue destruction, intermittent pain may be noticed during ongoing exposure. The dull continuous ache evolves into a throbbing sensation in 48 to 72 hours. This often persists until tissue demarcation several weeks to months later.

Chilblains (pernio) is a mild form of cold injury that often follows repetitive exposure. These “cold sores” appear less than 24 hours after exposure and usually affect facial areas, the dorsa of the hands and feet, and the pretibial areas. Young women with a history of Raynaud’s phenomenon or systemic lupus erythematosus or with antiphospholipid antibodies are especially at risk. Persistent vasospasm and vasculitis result in burning, pruritus, erythema, and mild edema. Plaques, blue nodules, and ulcerations can develop and last 1 to 2 weeks.

The other common nonfreezing cold injury is trench foot (immersion foot). This remains a significant threat during recreational activities and expeditions in cold, wet climates. Trench foot is produced by prolonged exposure to wet cold at temperatures above freezing. It usually develops slowly over several days and results in neurovascular damage in the absence of ice crystal formation. Immersion foot commonly develops while a person is wearing sweat-dampened or neoprene socks, vapor-barrier boots, or constrictive gaiters. Patients who soak their feet for hours each night in cool water for pain relief are at risk.

The clinical presentation varies. Most patients’ symptoms include cool, pale feet that are numb or tingle. Later the feet appear cyanotic, cold, and edematous. Often, numbness and leg cramping are present. The clinical hallmark is that after rewarming, the skin remains erythematous, dry, and very painful to touch. Rubor on dependency and pallor on elevation are caused by vasomotor paralysis.

Bullae that are indistinguishable from those seen with frostbite commonly develop. Vesiculation proceeds to ulceration and liquefaction gangrene in severe cases. Protracted symptoms of pain during weightbearing, cold sensitivity, and hyperhidrosis often last for years. Prevention of trench foot often simply requires continual drying of socks.

Classically, the initial presentation of frostbite is deceptively benign. Most patients do not arrive in the emergency department with frozen, insensate tissue. Frozen tissues often appear mottled or violaceous-white, waxy, or pale yellow. In severe cases, the examiner will not be able to roll the dermis over bony prominences. Rapid rewarming results in an initial hyperemia, even in severe cases. After thawing, partial return of sensation should be expected until blebs form.

Favorable initial symptoms include normal sensation, warmth, and color. Soft, pliable subcutaneous tissue suggests a superficial injury. A residual violaceous hue after rewarming is ominous. Early formation of clear large blebs that extend to the tips of the digits are more favorable than delayed appearance of smaller hemorrhagic blebs. These dark vesicles are produced by damage to the subdermal vascular plexi. Vesicles and large bullae eventually form in 6 to 24 hours.

Lack of edema formation suggests significant tissue damage. Post-thaw edema usually develops in less than 3 hours. In severe cases, frostbitten skin forms an early black, dry eschar until mummification and apparent demarcation.

Historically, frostbite, like burns, has been classified into degrees of injury. Anesthesia and erythema are characteristic of first-degree frostbite. Superficial vasculature appears by edema and erythema is considered second-degree. Third-degree frostbite produces deeper hemorrhagic vesicles. Fourth-degree injuries extend into subcuticular, osseous, and muscle tissues.

Classification by degrees is often incorrect in relation to the actual severity of the frostbite and thus therapeutically misleading. Mills suggests two simple retrospective classifications. Superficial or mild frostbite does not entail eventual tissue loss, whereas deep or severe frostbite does result in tissue loss. As a result, it is not feasible to predict, on presentation, the eventual tissue loss. Another classification attempts to establish severity based on clinical features coupled with early bone scan results.

## Diagnostic Strategies

Many ancillary diagnostic imaging techniques attempt to diagnose the severity of injury. Unfortunately, none consis-
tently and accurately predict tissue loss at the time of initial examination.

Routine baseline radiographs should be obtained, and at follow-up radiographs will begin to demonstrate specific frostbite abnormalities 4 to 10 weeks after injury. Intravenous isotope studies have mixed success experimentally and clinically. In one study, triple-phase bone scans performed 2 days after cold injury demonstrate ischemic tissue at risk. Delayed bone scans in 7 to 10 days can image deep tissue and bone infarction. The absence of radionuclide uptake even after 10 days, however, does not reliably predict the eventual need for amputation. The patient should be advised that accurate prediction of eventual tissue loss is difficult. As an ancillary tool, scintigraphy predicts the eventual demarcation line better than thermography. Scintigraphy as early as day 2 may predict tissue loss and monitor the efficacy of treatment.

Large vessel angiography does not assess the microvasculature at presentation because of vasospasm. Papaverine may help distinguish vasospasm from frostbite sludging and vascular injury. Transitory vascular instability often lasts 2 to 3 weeks. Angiography does facilitate evaluation of associated traumatic or chronic vascular abnormalities. Doppler ultrasonography and digital plethysmography are insensitive but may help determine the need for sympathetic blockade.

In clinical practice, magnetic resonance imaging and magnetic resonance angiography may be superior to technetium bone scanning. In one study, the clear-cut line of demarcation was noted before clinical demarcation.

**MANAGEMENT**

Field rewarming of frozen tissue is rarely practical. If possible, constricting or wet clothing should be removed and affected areas insulated and immobilized. Friction massage is not efficacious and increases tissue loss. Frozen parts should be kept away from dry heat sources in the transport vehicle to prevent a gradual partial thaw.

A direct relationship exists between the length of time that tissue is frozen and the ultimate extent of cellular damage. Rewarming should not be initiated in the field, however, if there is any potential for interrupted or incomplete thawing. Tissue refreezing is disastrous, and it is preferable to ambulate to safety on frozen extremities if rescue will be delayed.

When evacuation is not possible, rapid field rewarming, preferably in water at 40° to 42°C, may be the only option. Logistic considerations include risks to the party, the availability of shelter and necessary equipment, and the anticipated mode of eventual transportation.

**Emergency Department**

**Prethaw**

Pertinent history regarding the ambient temperature, wind velocity, and duration of exposure should be obtained. The type of apparel worn, the circumstances surrounding rescue, and the presence of preexisting cardiovascular or neurologic diseases that could affect tissue loss should be noted.

After stabilizing the core temperature and addressing associated conditions, rapid thawing should be initiated. Treatment should not be delayed while awaiting the results of laboratory and radiographic studies. Most patients have some degree of dehydration and benefit from crystalloid administration. Poor oral intake and hypothermia-induced cold diuresis further increase blood viscosity and sludging.

**Thaw**

Frozen or partially thawed tissue should be rapidly and actively rewarmed by immersion in gently circulating water that is carefully maintained at a temperature of 40° to 42°C by thermometer measurement. Marginal tissue can be thermally injured when the water temperature exceeds 42°C. Although a circulating tank is ideal for the extremities, a large container suffices for the hands or feet. In some cases, 35° to 40°C water is better tolerated and less painful.

Incomplete thawing and increased tissue loss are hazards when lower water temperatures are used. Rewarming should be continued until the part feels pliable and distal erythema is noted. This usually requires 10 to 30 minutes of submersion. Active gentle motion of the part by the patient during rewarming should be encouraged, but avoid direct tissue massage.

Parenteral analgesia is often indicated during rewarming of deep frostbite. Reperfusion is intensely painful. It produces throbbing, burning pain, and tenderness. A common error is premature termination of rewarming, which results in a partial thaw. Sensation is often diminished after thawing until it disappears without bleb formation.

Patients with completely frozen extremities are invariably hypothermic and at risk for significant fluid and electrolyte fluxes during rewarming. The acute thawing of large amounts of distal musculature extinguishes peripheral vasoconstriction. This results in the sudden return of cold, hyperkalemic, acidic blood to the central circulation. This produces “core temperature after-drop,” which is dysrhythmogenic. In the most severe cases, extracorporeal rewarming should be considered to manage these massive metabolic and electrolyte derangements (Box 137-3).

**Post-thaw**

The injured extremities must be kept elevated to minimize edema formation. Sterile dressings should be applied and

---

**BOX 137-3 EMERGENCY DEPARTMENT REWARMING PROTOCOL**

**Prethaw**

- Assess Doppler pulses and appearance
- Protect part—no friction massage
- Stabilize core temperature
- Address medical and surgical conditions
- Rehydrate patient
- Prevent partial thaw and refreeze

**Thaw**

- Provide parenteral ketorolac and analgesia
- Administer ibuprofen 400–600 mg q 6 hours PO
- Immerse part in circulating water that is thermometer-monitored at 37° to 40°C
- Encourage gentle motion of part

**Post-thaw**

- Dry and elevate part
- Aspirate or débride clear vesicles
- Débride broken vesicles and apply topical antibiotic or sterile aloe vera ointment every 6 hours
- Leave hemorrhagic vesicles intact
- Consider tetanus and streptococcal prophylaxis
- Provide hydrotherapy at 37°C tid
- Consider phenoxybenzamine in severe cases
- Consider imaging, angiography, and thrombolysis
- Obtain admission and serial photographs
involved areas handled gently. Persistent cyanosis in the extremities after a complete thaw may reflect increased fascial compartment pressure. Because of the cold-induced anesthesia, other occult soft tissue injuries are often not appreciated by the patient or physician. Tissue pressures should be monitored carefully, although decompressing escharotomies are usually not necessary during the initial treatment rendered in the emergency department.

The clinical role of thromboxane inhibition in frostbite is limited. Thromboxane inhibition does not appear to result in additional clinically significant tissue salvage. In one experimental model, methimazole did not improve tissue survival even when therapy was initiated immediately. Progressive secondary dermal ischemia is addressed by attempts to limit the accumulation of the products of arachidonic acid breakdown. Topical aloe vera (Dermaide) every 6 hours is a specific thromboxane inhibitor when applied directly to frostbitten areas but has not definitively been proven to salvage tissue. Other alternatives include topical antibiotic ointment. Systemically, ibuprofen appears preferable to salicylates. Although both agents inhibit this cascade, ibuprofen also produces fibrinolysis. Parenteral ketorolac should also be considered.

Frostbite blister management varies widely. Earlier recommended options for large clear blisters included leaving them intact, débridement, or aspiration (Fig. 137-1). Although all clinicians débride broken blisters, many prefer to aspirate intact clear blisters rather than leaving them intact. In contrast, if hemorrhagic blisters are débrided, secondary desiccation of deep dermal layers appears to extend the injury (Fig. 137-2). In this case, aspiration is preferable to débridement.

In severe cases, parenteral penicillin is indicated for streptococcal prophylaxis. Cultures and Gram stains of areas adjacent to the damaged tissue should be performed. Common organisms include staphylococci, streptococci, and *Pseudomonas* species. Broad-spectrum prophylaxis should be considered if excessive heat was used to thaw tissue, since liquefaction and infection are inevitable. Tetanus can also occur after frostbite.

Management of the chilblains syndrome is usually supportive. Nifedipine (20–60 mg daily) is an effective treatment for refractory perniosis. Topical or systemic corticosteroids have also been useful. Other options include oral pentoxifylline or limaprost, a prostaglandin E₁ analogue.

### Adjunctive Treatment

Numerous ancillary modalities have been suggested for frostbite. The only treatment consensus is removal from the cold and rapid complete thawing in a 40° to 42° C bath.

Capillary flow ceases early after cold injury, whereas thrombosis proceeds. This observation has led to multiple experimental antithrombotic and vasodilation treatment regimens, although most lack adequate controls. Most of these studies were conducted before the elucidation of some of the pathophysiologic consequences of frostbite. As demonstrated in a pilot study on triple-phase bone scans, thrombolytic agents may restore some flow to severely frostbitten limbs. The fibrinolytic agent urokinase can also conserve slowly thawed tissue.

In one study, intravenous tissue plasminogen activator and heparin reduced predicted digit amputations in severe frostbite. Nonresponders had over 24 hours of exposure, over 6 hours of warm ischemia, or multiple freeze-thaw cycles. In another study, intra-arterial tissue plasminogen activator decreased the incidence of amputations when administered within 24 hours.

Low-molecular-weight dextran may inhibit intravascular cellular aggregation. Animal models suggest that low-molecular-weight dextran is not harmful. Pentoxifylline, a phosphodiesterase inhibitor, may decrease blood viscosity and increase tissue oxygenation. Its ability to increase red blood cell flexibility facilitates revascularization and may enhance tissue survival. The suggested dosage is 400 mg three times daily for 2 to 6 weeks.

Various anti-inflammatory drugs and other agents have not been conclusively evaluated. These include steroids, nonsteroidal anti-inflammatory drugs, dipyridamole, dimethyl sulfoxide, nonionic detergents, and calcium channel blockers. A long-acting alpha-blocker, phenoxybenzamine, may decrease vasospasm while increasing peripheral blood flow. The dosage starts with 10 mg/day to a maximum of 60 mg/day. With this agent, adequate hydration is necessary to prevent orthostatic hypotension.

Hyperbaric oxygen produces vasoconstriction and subsequently reduces cutaneous blood flow. A small number of patients report a temporary flush and increased limb motion, but this appears to depend on the elapsed time interval after injury. Hyperbaric oxygen could accelerate demarcation. Insufficient data on severe frostbite exist to assess the potential value of hyperbaric oxygen therapy for tissue salvage.
Sympathectomy

The theoretical benefits of sympathectomy include relief of painful vasospasm, decreased edema, and tissue salvage. Long-term vasodilation could protect against repeated cold injury and some of the degenerative sequelae of frostbite. The value of these benefits is speculative. Epidural spinal cord stimulation combined with conventional treatment may reduce pain and conserve tissue.

A “medical” sympathectomy results from direct injection of an agent such as reserpine into an artery. Common injection sites include the radial, brachial, and femoral arteries. This injection produces local depletion of arterial wall norepinephrine for 2 to 4 weeks. No significant systemic effects are appreciated with the recommended dose of 0.5 mg. This can be repeated in 2 to 3 days. Parenteral reserpine is not commercially available in the United States. Guanethidine is an alternative.

There is angiographic documentation of temporary improvement in perfusion and vasospasm after medical sympathectomy. When tissue is rapidly thawed, experimental attempts to demonstrate further enhancement of tissue salvage have failed. Intra-arterial reserpine may prove most useful in patients with residual pain after gradual thawing.

Early results with surgical sympathectomy were encouraging. Decreased pain, edema, and residual autonomic dysfunction were reported. Tissue demarcation also appeared to accelerate. Bouwman and colleagues performed unilateral surgical sympathectomy on 10 patients with bilateral matched frostbite injuries. Delayed protection against reinjury was one direct benefit. Ultimately, however, there was no increased tissue salvage. Mills observes that surgical sympathectomy produces a smoother initial clinical course but no long-term benefits, with the possible exception of decreased causalgia.18,19

DISPOSITION

Except in minor cases, all patients should be hospitalized to determine the extent of injury. Superficial injuries to facial structures may be followed on an outpatient basis. Damaged tissues are best protected with loose sterile sheets and towels rather than compressive dressings. Feet must be kept elevated under a protective cradle. Sterile cotton pledges should be placed between the toes, and the hands may rest elevated on the chest.

Whirlpool hydrotherapy with an antiseptic should be performed two to three times daily for 20 to 30 minutes. Range-of-motion exercises should be encouraged during immersion. Severe cases may require position-of-function splinting. Hydrotherapy is continued as the eschar sloughs. At this point, sterile precautions may be discontinued. During hospitalization, all vasoconstrictive agents, including nicotine, should be avoided.

SEQUELAE

Direct neuronal damage and residual abnormalities in sympathetic tone are responsible for most of the common symptomatic sequelae of frostbite. In a series of military patients with documented frostbite, 65% had long-term residual symptoms. Vasospasm with secondary cold intolerance is the other major sequela.51

Intermittent paresthesias resulting from ischemic neuritis are reported after the first week. The severity of this symptom often reflects the extent of tissue damage. Symptoms may persist for many months. Burning electric shock sensations are worse at night, after heat exposure, and on first returning to ambulation. Thermal perception is also altered. Hyperhidrosis suggests an abnormal sympathetic nervous system response and often serves as both a cause and an effect of frostbite.

Delayed cutaneous findings include nail deformities and pigmentation changes. Squamous and epidermoid cell carcinoma can occur. Osseous reabsorption and subchondral lytic defects develop months after the cold insult. In pediatric patients, concerns include premature fusion, destruction, and fragmentation of epiphyses. Shortening of the distal phalanges is common.51 Frostbite arthritis also occurs, commonly 3 to 10 years later. Thumb sparing is a characteristic idiosyncrasy. Clenching of the fists can spare both thumbs and metacarpophalangeal joints. Identification of subchondral cysts following bone infarction differentiates frostbite arthritis from osteoarthritis.52 In severe cases involving extremity muscle compartments, rhabdomyolysis and subsequent renal failure are a concern. Continuous monitoring of serum muscle enzymes and urinalyses is warranted.

Surgical decisions regarding amputation are complex. The amount of tissue eventually salvaged often exceeds even optimistic initial estimates. Historically, the natural progression of demarcation, mummification, and eventual sloughing was allowed to occur. Necrotic tissue was classically débrided at least 1 to 2 months after injury when the line of demarcation was clear. Exceptions include refractory pain, sepsis, and supervening gangrene. Advances in radiologic assessment of tissue viability are facilitating earlier surgical intervention. Most grafts and amputations now occur at 3 to 4 weeks after injury. Free flap tissue transfer to salvage function after earlier débridement of soft tissues should be a consideration. Various neuropathic, musculoskeletal, and dermatologic sequelae of frostbite are listed in Box 137-4.

**KEY CONCEPTS**

- Premature termination of thawing in 40° to 42° C water is a common error. Reperfusion of completely frozen tissue is very painful and will require parenteral analgesia.
- The early formation of clear blebs is more favorable than delayed hemorrhagic blebs, since the latter reflect damage to the subdermal vascular plexi.
- The patient should be advised that accurate prediction of eventual tissue loss is not always possible at presentation, despite imaging.
- Thrombolytic agents may restore some flow to severely frostbitten limbs.

Accidental Hypothermia

Daniel F. Danzl

The “reanimations” of profoundly cold victims in prolonged cardiac arrest help explain the contemporary allure of hypothermia. A physician was successfully resuscitated from accidental hypothermia at 13.7°C after a 9-hour resuscitation. This included cardiopulmonary resuscitation (CPR) initiated at the scene and 179 minutes of cardiopulmonary bypass.

Although used for medical purposes for millennia, cold modalities were not scientifically evaluated until the 18th century. The hemostatic, analgesic, and therapeutic effects of cold were well known. Accidental hypothermia was also common and its treatment controversial. Biblical references cite truncal rewarming of King David by a damsel, and various remedies, including rubbing the extremities with hot oil, were mentioned by Hippocrates, Aristotle, and Galen.

Cold weather has had a major impact on military history. Hannibal lost nearly half of his army of 46,000 while traversing the Pyrenees Alps in 218 BCE. Baron Larrey, Napoleon’s chief surgeon, reported that only 350 of the 12,000 men in the 12th division survived the cold during their retreat from Russia in 1812. Those soldiers who were rapidly rewarmed closest to the campfire died.

The winter of 1777 took its toll on Washington’s troops at Valley Forge. The French subsequently suffered heavy losses to the cold in the Crimean War (1845–1855). These lessons were relearned during both world wars. Many pilots and U-boat crews perished from the cold water in the North Atlantic. Approximately 10% of the U.S. casualties in Korea were cold related.

Innumerable cold-related tragedies affect both military personnel and civilians, in particular hunters, sailors, skiers, climbers, boaters, and swimmers. Widespread participation in outdoor winter sports increases the number of patients who develop hypothermia.

Hypothermia is geographically and seasonally pervasive. Most cases occur in urban settings. “Primary” hypothermia fatalities are classified as accidental, homicidal, or suicidal. Death certificate data, however, under-report secondary hypothermia deaths, in which cold complicates many systemic diseases. The effect of cold on mortality from cardiovascular and neurologic disorders is greatly underestimated.

Hypothermia is defined as a core temperature less than 35°C. Many variables contribute to the development of accidental hypothermia. Exposure, age, health, nutrition, medication, and intoxicants can decrease heat production, increase heat loss, or interfere with thermoregulation. The healthy individual’s compensatory responses to heat loss through conduction, convection, radiation, and evaporation are often overwhelmed by exposure. Medications can also interfere with thermoregulation, and central nervous system (CNS) processes commonly decrease the efficiency of thermoregulation.

PRINCIPLES OF DISEASE

Physiology of Temperature Regulation

Human basal heat production generates approximately 40 to 60 kcal/m² of body surface area per hour. This increases with food ingestion, muscular activity, fever, and acute cold exposure. Cold stress increases preshivering muscle tone, and heat production can double. Maximal heat production lasts only a few hours because of fatigue and glycogen depletion.

Shivering thermogenesis increases the basal metabolic rate two to five times. This shivering, which markedly increases oxygen consumption, is modulated by the posterior hypothalamus and the spinal cord.

The preoptic anterior hypothalamus orchestrates nonshivering heat conservation and dissipation. Serotonergic and dopaminergic neurons are pivotal. They exert immediate control through the autonomic nervous system and delayed control through the endocrine system. Thermal suppression or activation of the sympathetic nervous system with cold-induced release of norepinephrine also occurs. Cold also stimulates the hypothalamus to release thyrotropin-releasing hormone. This activates the anterior pituitary gland, which releases thyroid-stimulating hormone, and results in the release of thyroxine from the thyroid gland.

The discomfort of cold can be reduced after long periods of exposure. No evidence exists, however, that there is any significant physiologic adaptation to the cold (Fig. 138-1).

Normal heat loss occurs through five mechanisms. Assuming an average basal metabolic rate, 55 to 65% of this loss is through radiation. Heat loss by radiation is greatest when one is spread nude and least when curled and insulated. Radiative heat loss depends on the temperature gradient between the environment and the exposed body surface area. Conduction normally accounts for only approximately 2 to 3% of the heat loss, but this may increase up to five times in wet clothing and up to 25 times in cold water.

Close correlation exists between subcutaneous fat thickness and cooling rates. Individuals with greater insulation lose heat more slowly. Conduction and convection normally account for
Figure 138-1. Physiology of cold exposure.

about 15% of the body’s heat loss, but convective losses increase with shivering. Respiration and evaporation account for the remainder of the loss, with 2 to 9% lost in heating inspired air and 20 to 27% lost to insensible evaporation from the skin and lungs.

Cutaneous and respiratory heat loss is markedly influenced by the ambient temperature, air motion, and relative humidity. Greater losses occur in a cool, dry, windy environment (wind-chill index). When the body is not perspiring, most heat loss is through radiation and convection. Conductive losses become significant in immersion-induced hypothermia. Children cool faster than adults because of the elevated ratios of surface area to mass.

When the temperature is between 37° and 32°C, vasoconstriction, shivering, and nonshivering basal and endocrinologic thermogenesis generate heat. From 32° to 24°C, a progressive depression of the basal metabolic rate occurs without shivering thermogenesis. At temperatures less than 24°C, autonomic and endocrinologic mechanisms for heat conservation become inactive.

Pathophysiology

Cardiovascular

After an initial tachycardia, a progressive bradycardia develops. The pulse usually decreases by 50% at 28°C. If an observed tachycardia is inconsistent with a patient’s temperature, associated conditions such as hypoglycemia, drug ingestion, or hypovolemia should be considered.

The bradycardia of hypothermia results from decreased spontaneous depolarization of the pacemaker cells. As a result, the bradydysrhythmia is refractory to atropine. Hypothermia also decreases the mean arterial pressure and the cardiac index.

The electrocardiographic features of hypothermia are unique.15,14 Initially described by Tomaszewski in 1938, the Osborn (J) wave is seen at the junction of the QRS complex and ST segment (Fig. 138-2). J waves are potentially diagnostic but not prognostic. They may appear at any temperature under 32°C. The size of the J wave is not related to arterial pH but does increase with temperature depression.

J waves are normally upright in the aVL, aVF, and left precordial leads.15 The J deflection may be a result of hypothermic ion flux alterations, with delayed depolarization or early repolarization of the left ventricular wall. It can also be seen during local cardiac ischemia and with sepsis or CNS lesions, hypercalcemia, and the Brugada syndrome.

Some J waveform abnormalities simulate a myocardial injury current. Hypothermic electrocardiographic changes are not easily computer programmable. Reliance on computer interpretations can result in mistaken thrombolysis, which would be expected to exacerbate preexistent coagulopathies.16

All atrial and ventricular dysrhythmias are common in moderate or severe hypothermia. Reentrant dysrhythmias result from decreased conduction velocity with increased myocardial conduction time and a decreased absolute refractory period. Independent electrical foci also precipitate dysrhythmias.

Because the conduction system is more sensitive to the cold than the myocardium, cardiac cycle prolongation occurs. Fluctuations of available oxygen, pH, electrolytes, and nutrients also alter conduction. As hypothermia worsens, the PR interval, then the QRS interval, and finally (and most characteristically) the QT interval become prolonged. In the absence of obvious shivering, thermal muscular tone may obscure P waves or produce artifacts.

Atrial fibrillation is common when the core temperature is less than 32°C. Other rhythms are sinus, atrial, or junctional. Atrial fibrillation usually converts spontaneously during rewarming, and mesenteric embolization is a hazard.

The development of ventricular fibrillation (VF) or asystole in hypothermia is multifactorial. Putative explanations include tissue hypoxia, physical jostling, electrophysiologic or acid-base disturbances, and autonomic dysfunction. Asystole and VF can occur spontaneously when the core temperature falls below 25°C.17,18 Hypothermia causes a decrease in transmembrane resting potential, which, in turn, decreases the threshold for ventricular dysrhythmias. VF can also result from an independent focus or a reentrant phenomenon. When the heart is cold, a large dispersion of repolarization exists, which facilitates the development of a conduction delay. The action potential is also prolonged, and this increases the temporal dispersion of the recovery of excitability.

The term core temperature afterdrop refers to a further decline in an individual’s core temperature after removal from the cold. The two processes that contribute to afterdrop are simple temperature equilibration across a gradient and circulatory changes. Countercurrent cooling of the blood, which is perfusing cold tissues, results in a temperature decline until the gradient is eliminated.19

Active external rewarming of the extremities obliterates peripheral vasoconstriction and reverses arteriovenous shunting. This is most vividly demonstrated by Hayward, who measured his own esophageal, rectal, tympanic, and cardiac temperatures (using a flotation tip catheter) after cooling in 10°C water on three different days.20 Warm bath immersion rewarming caused a 30% fall in mean arterial pressure, coupled with a 50% decline in peripheral vascular resistance.

Core temperature afterdrop is a clinically relevant consideration when treating patients with a large temperature gradient between the core and the periphery. This is common in patients who are dehydrated after chronic exposure. Major afterdrops also occur in severely hypothermic patients if frostbitten extremities are thawed before thermal stabilization of the core.

Central Nervous System

Hypothermia progressively depresses the CNS.21 Significant alteration of the brain’s electrical activity begins below 33.5°C, and the electroencephalogram silences at 19° to 20°C.
Cerebral autoregulation is maintained with an increase in vascular resistance until 25°C. In cases of severe hypothermia, there is a disproportionately higher redistribution of blood flow to the brain. Visually evoked potentials are an objective measure of cerebral function and depend on cerebral blood flow. The potentials become smaller as the temperature decreases. Like the heart, the brain has a critical period of tolerance to hypothermia. There are temperature-dependent neural enzyme systems that are unable to function at temperatures that are well tolerated by the kidney.

**Renal System**
Simple exposure to cold induces a diuresis regardless of an individual’s state of hydration. Hypothermia depresses renal blood flow, reducing it by 50% at 27° to 30°C. The kidneys then excrete a large amount of dilute urine, termed cold diuresis. Cold diuresis is essentially glomerular filtrate, which does not clear nitrogenous waste products. Severe hypothermia causes an initial relative central hypervolemia as a consequence of peripheral vasoconstriction. Cold diuresis may act as a volume regulator to diminish the vasoconstriction-induced capacitance vessel overload. Cold water immersion can further increase urinary output by 3.5 times, and ethanol doubles that increase.22

**Respiratory System**
Hypothermia initially stimulates respiration. This is followed by a progressive decrease in the respiratory minute volume, which is proportional to the decreasing metabolism. Carbon dioxide production decreases 50% with an 8°C fall in temperature. The normal stimuli for respiratory control are altered in severe hypothermia, and carbon dioxide retention with respiratory acidosis can occur.

Numerous other pathophysiologic factors adversely affect the respiratory system (Table 138-1). These include viscous bronchorrhea, decreased ciliary motility, and noncardiogenic pulmonary edema.

**Predisposing Factors**
Predisposing factors that contribute to the pathophysiologic changes accompanying core temperature depression can be categorized as those that decrease heat production, increase heat loss, or impair thermoregulation (Box 138-1).

**Decreased Heat Production**
Decreased thermogenesis is often secondary to an endocrinologic failure such as hypopituitarism, hypoadrenalism, or myxedema. Myxedema coma is several times more common in women, and up to 80% of these persons are hypothermic. Hypothyroidism is often occult in this setting. There is usually no available history of lassitude, dry skin, arthralgias, or cold intolerance.

Hypoglycemia with central neuroglycopenia also predisposes to hypothermia. Another cause of decreased heat production is malnutrition, which corresponds to a decrease in subcutaneous fat. Severe malnutrition, as with marasmus, contributes to heat loss. Kwashiorkor is less commonly associated with hypothermia because of the insulating effect of the hypo-proteinemic edema.12

The young and the old are commonly at risk. The neonate has a large surface area-to-mass ratio, a relatively deficient subcutaneous tissue layer, and an inefficient shivering mechanism. Since neonates lack behavioral defense mechanisms, they are more likely to develop hypothermia.

Acute neonatal hypothermia is common after emergency deliveries or resuscitations. Many neonates are lethargic, fail
Chapter 138 / Accidental Hypothermia

**Factors Predisposing to Hypothermia**

- Decreased heat production
- Endocrinologic failure
- Hypopituitarism
- Hypoadrenalism
- Hypothyroidism
- Diabetes
- Insufficient fuel
- Hypoglycemia
- Malnutrition
- Marasmus
- Kwashiorkor
- Extreme exertion
- Neuromuscular inefficiency
- Age extremes
- Impaired shivering
- Inactivity
- Lack of adaptation
- Increased heat loss
- Environmental
- Immersion
- Nonimmersion
- Induced vasodilation
- Pharmacologic
- Toxicologic
- Erythrodermas
- Burns
- Psoriasis
- Ichthyosis
- Exfoliative dermatitis
- Iatrogenic
- Emergency deliveries
- Cold infusions
- Heatstroke treatment
- Impaired thermoregulation
- Peripheral failure
- Neuropathies

</table>
to thrive, and have a weak cry. Half have deceptively rosy cheeks. Late-onset hypothermia, which occurs after 72 hours of life, is commonly a result of septicemia. Hypothermia can occur in the shaken baby syndrome and may be a factor in some cases of apparent sudden infant death syndrome.

Homeostatic capability progressively decreases with aging. Thermal perception is altered, and elderly people manipulate the indoor ambient temperature less precisely. Most elderly patients are capable of normal thermoregulation but are prone to conditions, including immobility and systemic diseases, which interfere with heat production and conservation. Evidence exists that normal aging factors can predispose to hypothermia. Inability to sense cold, abnormal adaptive behavioral responses, and decreased peripheral blood flow reflect geriatric autonomic dysfunction.23-25

### Increased Heat Loss

Many individuals often conserve heat poorly during exposure to the cold. Patients with erythrodermias, including psoriasis, exfoliative dermatitis, ichthyosis, eczema, and burns, can have increased peripheral blood flow. Iatrogenic causes of heat loss include exposure during resuscitations, massive cold infusions, overcooling of patients with heat stroke, and overzealous burn treatment.

Ethanol is metabolized at a slower rate in hypothermic individuals and interacts with every putative thermoregulatory neurotransmitter. It may directly damage the posterior hypothalamus and the mammillary bodies. Cutaneous heat loss increases through vasodilation, and shivering thermogenesis is decreased.

Ethanol is the most common cause of heat loss in urban settings.8,17 Patients often lack protective adaptive behavior to avoid the cold. “Paradoxical undressing,” which is the removal of clothing in response to a cold stress, is common.26 Aging is associated with an increased sensitivity to the hypothermic actions of ethanol. Hypothalamic alcoholic ketoacidosis also occurs. The incidence of hypothermia in patients with Wernicke’s encephalopathy is common. Hypothermia can mask the usual clinical triad of ophthalmoplegia, confusion, and truncal ataxia. Intravenous thiamine can be both diagnostic and therapeutic.

### Impaired Thermoregulation

Thermoregulation can be impaired centrally, peripherally, or metabolically. Skull fractures, particularly basilar fractures, and chronic subdural hematomas are implicated. Other causes include cerebrovascular accidents, neoplasms, anorexia nervosa, and Hodgkin’s and Parkinson’s diseases. The final common pathway in these disorders may be centrally mediated vasodilation. Cerebellar lesions produce choreiform, less efficient shivering.

In therapeutic or toxic doses, antidepressants, antinmamic agents, antipsychotics, anxiolytics, and general anesthetics interfere with thermoregulation by impairing centrally mediated vasoconstriction. Overdosage of these medications and others (e.g., the organophosphates, heroin, glutethimide, and carbon monoxide) predisposes to hypothermia.

Peripheral thermoregulatory failure classically occurs after acute spinal cord transection. The interruption of the autonomic nervous system eliminates vasoconstrictive control and the patient effectively becomes poikilothermic. Neuropathies and diabetes are additional peripheral causes of heat loss. An abnormal plasma osmolality may explain hypothalamic interference in uremia, lactic acidosis, diabetic ketoacidosis, and hypoglycemia.27

### Miscellaneous Causes

Hypothermia occurs in conjunction with several infections, most commonly overwhelming gram-negative sepsis, pneumo-

nia, meningitis, and encephalitis. Other associated infections include bacterial endocarditis, brucellosis, malaria, syphilis, typhoid, miliary tuberculosis, and trypanosomiasis.

Medical conditions associated with hypothermia include carcino-

ma, pancreatitis without secondary infection, peritonitis from any cause, and severe cerebrovascular disease. Low cardiac output resulting from a myocardial infarction can induce hypothermia. Fetal and maternal bradycardia and hypothermia may result from magnesium sulfate infusion during preterm labor. Delayed recovery from neuromuscular blockade may also result from unrecognized hypothermia.

### Traumatic Factors

Following trauma, hypotension and hypovolemia jeopardize thermosatility.28 In patients with major injuries, a fall in core and skin temperature with no compensatory shivering thermogenesis occurs. Thermoregulation is impaired, and heat production decreases.

Hypothermia may exacerbate blood loss by inducing a coag-

ulopathy via three mechanisms: the coagulation cascade of enzymatic reactions is impaired, plasma fibrinolytic activity is enhanced, and platelets are sequestered and poorly functional.29

Traumatic injuries may be overlooked if hypotension or neurologic findings such as areflexia or paralysis are misattrib-utated to hypothermia. Major risk factors for hypothermia in trauma patients include age; type of injury; level of intoxi-
cants; transfusion requirements; and elapsed time spent in the field, emergency department, and operating room.

Hypothermia can only protect the brain from ischemia when it is induced before shock develops. This reduces adenosine triphosphate (ATP) use while the ATP stores are near normal. In traumatized patients, the ATP stores are already depleted. The target core temperature when rewarming a patient with an isolated head injury should balance neuroprotection against the adverse hematologic and immunologic consequences of hypothermia.30

### CLINICAL FEATURES

When exposure is obvious, the diagnosis is simple. Apprecia-
tion of more subtle presentations helps facilitate the early diagnosis of mild to moderate hypothermia. Vague symptoms include hunger, nausea, confusion, dizziness, chills, pruritus, or dyspnea (Box 138-2). During an expedition, individuals may simply become uncooperative, uncoordinated, moody, or apathetic. Indoors, elderly patients may exhibit confusion or simply become less communicative and display lassitude or a peculiar “flat” affect. Subtle progression of mental deterioration or motor skill impairment may mimic senility. Symptoms such as slurred speech and ataxia may resemble symptoms of a cerebrovascular accident or intoxication.27

Some elderly people have a decreased ability to sense cold and thus fail to take appropriate adaptive action. The maladaptive phenomenon of paradoxical undressing is not uncommon.26 The last preterminal effort of the victim may be related to the peripheral vasoconstrictive changes of profound hypothermia. The patient can be mistaken for a victim of sexual assault.

In urban settings, hypothermia is most commonly associated with ethanol ingestion or underlying illness. Other common presentations include strokes, overdoses, psychiatric emergencies, or coexistent major trauma.17

Neurologic manifestations vary widely. A progressive decrease in the level of consciousness is usually proportional to the degree of hypothermia. Some patients, however, continue to be verbally responsive and display intact reflexes at 27° to 25°C. Eye movement abnormalities and extensor plantar responses do not correlate directly with the degree of hypothermia. Cranial nerve signs may be seen with bulbar damage from central pontine myelinolysis. Above 22°C, it should be assumed that nonreactive dilated pupils reflect inadequate tissue perfusion and not hypothermia per se.

The rest of the neuromuscular examination may suggest the diagnosis. The patient's posture ranges from stiff to pseudo-rigor mortis to opisthotonus. Reflexes are usually hyperactive down to 32°C, then become hypoactive until they disappear around 26°C. Cremasteric reflexes are expectedly absent with testicular retraction. The plantar response usually remains flexor until 26°C. The knee jerk, when intact, is the last reflex to disappear and the first to reappear with rewarming. The diagnosis of an antecedent CNS disorder, including cord lesions, may be obscured by hypothermia.

Between 30° and 26°C, both contraction and relaxation phases of the reflexes are equally prolonged. If intact, the ankle jerk is helpful in diagnosing hypothermic myxedema. Myxedema prolongs the relaxation phase more than the contraction phase.

No psychiatric disorder improves when the patient is cold. Mental status alterations include anxiety, perseveration, neurosis, and psychosis. Many individuals who are functional in temperate climates decompensate in colder weather. Hypothermic-induced psychiatric presentations and suicide attempts are commonly misdiagnosed.12

#### DIAGNOSTIC STRATEGIES

**Laboratory Evaluations**

**Acid-Base Balance**

Blood gas analyzers warm blood to 37°C, which increases the partial pressure of dissolved gases. This results in an arterial blood gas (ABG) report showing higher oxygen and carbon...
dioxide levels and a lower pH than the patient’s actual values. Optimal ABG levels in the setting of hypothermia dictate that correction of ABGs for temperature is unnecessary as a guide to therapy. In fact, attempting to maintain a corrected pH at 7.4 and arterial partial pressure of carbon dioxide (PaCO₂) at 40 mm Hg during hypothermia depresses cerebral and coronary blood flow and cardiac output and increases the incidence of ventricular fibrillation. The ideal acid-base strategy is the ectothermic alpha-stat approach. Simply put, the goal is an uncorrected pH at 7.4 and PaCO₂ at 40 mm Hg.

Cold blood buffers poorly. In normothermia, when the PaCO₂ increases 10 mm Hg, the pH decreases 0.08 units. At 28°C, the decrease in pH doubles. Because the neutral point of water at 37°C is a pH of 6.8, the normal 0.6-unit pH offset between blood and intracellular water should be maintained at all temperatures. Just as the neutral pH rises with cooling, so should actual blood pH (Fig. 138-3).

Intracellular electrochemical neutrality ensures optimal enzymatic function at all temperatures. Relative alkalinity affords myocardial protection and improves the heart’s electrical stability. Carbogen could prove valuable in the treatment of accidental hypothermia because it flattens and shifts the oxyhemoglobin dissociation curve to the right.

**Hematologic Evaluation**

A patient’s hematocrit can be deceptively high as the result of the decreased plasma volume. The hematocrit level increases 2% for every 1°C fall in temperature. A low-normal hematocrit level in a moderate to severely hypothermic patient should suggest acute blood loss or the possibility of a preexisting anemia.

A normal white blood cell count never excludes infection, especially if the patient is debilitated, alcoholic, myxedematous, or at either age extreme. Splenic, hepatic, and splanchnic sequestration in hypothermia decreases leukocyte and platelet counts.

Frequent evaluation of serum electrolytes during rewarming is essential. There are no safe predictors of their values or trends. Changes occur in both membrane permeability and in the sodium-potassium (K⁻:Na⁺) pump. The patient’s preexisting physiologic status, the severity and chronicity of hypothermia, and the method of rewarming alter the serum electrolyte values.

The plasma potassium level is independent of the primary hypothermic process. Hyperkalemia is often associated with metabolic acidosis, rhabdomyolysis, or renal failure. An important caveat is that hypothermia enhances the cardiac toxicity and obscures the premonitory electrocardiographic changes associated with hyperkalemia.

Hypokalemia is most common with chronic hypothermia. It results from potassium entering muscle, not a kaliuresis. A discrepant decline in serum potassium level despite a decreasing serum pH is caused by intracellular pH fluxes greater than extracellular pH fluxes.

Conditions associated with hypokalemia include preexisting diabetic ketoacidosis, hypopituitarism, inappropriate secretion of antidiuretic hormone, previous diuretic therapy, and alcoholism. If the potassium level is less than 3 mEq/L, supplementation may be necessary for treatment of gastrointestinal ileus or congestive heart failure during rewarming.

The blood urea nitrogen (BUN) and creatinine levels are elevated with preexisting renal disease or decreased clearance. Because of hypothermic fluid shifts, the hematocrit and BUN levels are poor indicators of a patient’s actual fluid status.

The blood sugar level may also provide a subtle clue to the type of hypothermia. Acute hypothermia initially elevates blood sugar levels through catecholamine-induced glycogenolysis, diminished insulin release, and inhibition of cellular membrane glucose carrier systems. On the other hand, subacute and chronic hypothermia produce glycogen depletion, leading to hypoglycemia. Symptoms of hypoglycemia can be masked by hypothermia. A cold-induced renal glycosuria does not imply hyperglycemia nor guarantee normoglycemia.

When hyperglycemia persists during rewarming, one should suspect hemorrhagic pancreatitis or diabetic ketoacidosis. Patients with the latter must be actively rewarmed past 30°C because insulin is ineffective below that temperature. Correction of hypoglycemia only corrects the level of consciousness because of the corresponding level of hypothermia.

Severe hypothermia also causes serum enzyme elevation because of the ultrastructural cellular damage. Rhabdomyolysis is commonly associated with cold exposure.

Ischemic pancreatitis may result from the microcirculatory shock of hypothermia. The decreased pancreatic blood flow then activates proteolytic enzymes. The amylase and lipase levels can correlate with mortality.

**Hypothermic Coagulation**

A physiologic increase in coagulation occurs with hypothermia, and a disseminated intravascular coagulation type of syndrome occurs. The cause may be catecholamine or steroid release, simple circulatory collapse, or release of tissue thromboplastin from cold, ischemic tissue.

Hypothermic patients also develop coagulopathies because the enzymatic nature of the activated clotting factors is depressed by the cold. The clotting prolongation is proportional to the number of steps in the cascade. Because the kinetic tests of coagulation are performed in the laboratory at 37°C, the physician will see a disparity between the in vivo clinically evident coagulopathy and the deceptively “normal” prothrombin time, partial thromboplastin time, or international normalized ratio (INR) reported by the laboratory. The only effective treatment is rewarming, not administration of clotting factors.

The leukopenia and thrombocytopenia usually reverse with rewarming. Clinically significant coagulopathies occur, partic-
ularly in association with trauma. Cold-induced thrombocytopenia is observed with induced hypothermia. The mechanism may be either direct bone marrow suppression or splenic and hepatic sequestration. Platelet thromboxane B2 production is also temperature dependent. Thrombocytopenia is more common at both age extremes.

The elevated viscosity seen with hypothermia may be exacerbated in patients with cryoglobulinemia or cryofibrinogenemia, both of which are more common in elderly patients. Cryofibrinogen, which is a cold-precipitated fibrinogen, is associated with the collagen vascular diseases, carcinomas, and coliform sepsis. The pathophysiology of cold hemagglutination results from cold agglutinins that produce either hemolysis or agglutination with thrombosis. This could explain the increase in coronary and cerebral thromboses in winter.

In summary, except in mild cases, the immediate laboratory evaluations should include glucose; ABGs uncorrected for temperature; complete blood cell count; a comprehensive metabolic panel including serum calcium, serum magnesium, and serum amylase/lipase levels; and coagulation studies. Baseline serum BUN and creatinine tests are indicated because renal failure may occur after rewarming in patients with chronic hypothermia.

A toxicologic screen is necessary by history or when the depression of the level of consciousness is inconsistent with the degree of hypothermia. Thyroid function studies, cardiac markers, and serum cortisol levels have selective utility.

The indications for radiography should be liberalized from normothermia. As examples, if the patient is not alert, spinal radiographs should be obtained. Bedside ultrasonography or computed tomography may show pancreatic calcifications, unsuspected pneumoperitoneum, small bowel dilation from hypothermia-induced mesenteric vascular occlusion, or colonic dilation associated with myxedema coma.

### MANAGEMENT

Patients who are cold, stiff, and cyanotic, with fixed pupils and inaudible heart tones, without visible thoracic excursions, continue to be successfully resuscitated. Embarrassingly, some patients still recover completely in the morgue.

An adequate history includes available pertinent information regarding preexisting cardiac, pulmonary, neurologic, or endocrinologic disease. The duration of exposure, circumstances of discovery, associated injuries, and predisposing conditions should be documented. Initial management should emphasize the prevention of further heat loss. The goals of prehospital care are to rescue, examine, insulate, and gently transport.

If the patient is unresponsive and not shivering, presume the hypothermia is severe. At temperatures below 32°C, one should expect an irritable myocardium, a temperature gradient between the core and periphery, and relative hypovolemia.

In the emergency department, hypothermia should be confirmed and monitored with continuous core temperature evaluation. Every emergency department should have the equipment to accurately measure the core temperature. Standard oral thermometers record only down to 35°C. Oral temperatures are unreliable if the patient is uncooperative or tachypneic, or if the ambient temperature is low. Clinically, the rectal temperature is the most practical; however, it can lag behind core changes and is influenced by lower extremity temperatures and probe placement. The probe should be inserted to 15 cm and not placed in cold feces.

The tympanic temperature equilibrates most rapidly with the core temperature and is closest to the hypothalamic temperature. Infrared thermography should not be used alone in the setting of suspected hypothermia because the reliability of commercially available devices remains uncertain. If the patient is tracheally intubated, an esophageal probe reads falsely high with heated inhalation.

A Doppler measuring device may be necessary to establish the presence of a spontaneous pulse or blood pressure. The accuracy of pulse oximetry during conditions of poor perfusion and hypothermia is uncertain. Similarly, end-tidal carbon dioxide measurements accurately assess tissue perfusion and tracheal tube placement only at normal temperatures. Commercially available devices do not function with humidified air used for airway rewarming.

Endotracheal intubation may be necessary unless the patient is alert or has intact protective airway reflexes. Cold depression of ciliary activity allows secretory accumulation, with the production of frothy sputum and chest congestion. Failure to differentiate between this bronchorrhea and pulmonary edema may explain the conflicting reports of the association of hypothermia with pulmonary edema. Nasotracheal intubation is a noninvasive option when cold-induced trismus is present, unless there is a significant coagulopathy.

In a multicenter survey, endotracheal intubation was performed on 117 patients by multiple operators in various settings. No induced dysrhythmias were recognized, as in several subsequent series. Factors commonly precipitating dysrhythmias include failure to preoxygenate, mechanical jostling, acid-base changes, and electrolyte fluctuations.

A nasogastric tube is indicated in patients with moderate and severe hypothermia after endotracheal intubation. Decreased gastric motility and gastric dilation occur commonly. Physical examination of the abdomen is unreliable because the cold can induce rectus muscle rigidity. A large percentage of moderate and severely hypothermic patients have decreased or absent bowel sounds. Because physical examination of the abdomen is unreliable, it is important to evaluate the patient carefully for an associated ileus, pancreatitis, or occult trauma.

In cases of moderate and severe hypothermia, indwelling bladder catheters with urine meter bags are essential to monitor urinary output and to help determine the severity of vascular fluid shifts.

Cardiac monitoring should be continued and peripheral or central intravenous catheters inserted as necessary. Inserting a central venous pressure catheter tip into the heart can precipitate dysrhythmias and should be avoided. Arterial catheters for continuous monitoring of intra-arterial blood pressure may rarely be necessary in selected profoundly hypothermic patients. The clinician should avoid placement of pulmonary artery catheters that risk perforation of the cold, stiff pulmonary artery.

### Volume Resuscitation

Patients with moderate or severe hypothermia are usually dehydrated, and they are also prone to thromboembolism resulting from the increased viscosity. During rewarming, a relatively high total plasma volume and low circulatory plasma volume are often present. As hypothermia develops, other effects include an increased peripheral vascular resistance with a decreased circulatory volume.

Rapid volume expansion is critical. In hypothermic neonates, the mortality risk is dramatically lessened. Adult patients with moderate or severe hypothermia should initially receive a 250 to 500 mL fluid challenge of heated 5% dextrose in normal saline solution pending laboratory analyses. Lactated Ringer’s solution should be avoided because the cold liver inefficiently metabolizes lactate.
Fluids administered intravenously should be heated to 40° to 42° C. This is done primarily to avoid worsening hypothermia, because the amount of heat provided only becomes significant with large-volume resuscitations. There are many commercially available fluid and blood warmers. If unavailable, another option is to microwave intravenous fluids in plastic containers. A 1-L bag of crystalloid requires an average of 2 minutes on high power. The fluid should be shaken before administration to avoid hot spots. Rapid central venous administration, which may produce myocardial thermal gradients, should also be avoided.

There can be significant conductive heat loss through intravenous tubing. Long lengths of this tubing increase heat loss, especially at slow flow rates. Countercurrent heat exchangers effectively heat crystalloids and blood from 10° to 35° C.

Normally, hypothermia induces an increased natriuresis. Preexisting gastrointestinal losses or previous diuretic treatment can also contribute to sodium loss. Patients with normal sodium and osmolality values may have preexisting sodium overload as a result of cirrhosis, nephrosis, or congestive heart failure; however, most patients will be free-water depleted, which elevates their sodium and osmolality values.

Hemoconcentration resulting from decreased plasma volume, fluid shifts, and increased vascular permeability usually is present. Hemoconcentration can occur from parenteral crystalloid administration, but a low hematocrit can also result from acute hemorrhage or preexisting anemia.

Advanced Life Support

Blood flow during CPR in patients with hypothermia differs from that during normothermia, when some flow results from phasic alterations in the intrathoracic pressure, not necessarily from direct cardiac compression. During hypothermic cardiac arrest in swine, the cardiac output and cerebral and myocardial blood flows average 50, 55, and 31%, respectively, of those achieved during normothermic closed-chest compressions.

In hypothermia, the heart is a passive conduit. The “thoracic pump” concept notes that the phasic alterations in the intrathoracic pressure are exerted equally on all cardiac chambers. The mitral valve remains patent during systole, and blood continues to circulate through the left side of the heart. This could explain the observation of Althaus and associates, who noted that in one of three survivors at thoracotomy, “the heart was found to be hard as stone and it is hardly conceivable how effective external cardiac massage could have been.” There are innumerable neurologically intact survivors after prolonged closed-chest compressions.

Chest wall elasticity and pulmonary compliance are decreased with cold. Therefore, more force is needed to depress the chest wall sufficiently to generate intrathoracic pressure gradients. Pneumatic-powered thoracic compression devices are useful during prolonged resuscitations pending decisions regarding extracorporeal rewarming. Other perfusion enhancers could include abdominal binding to inhibit paradoxical diaphragmatic motion and simultaneous compression ventilation.

Tissue decomposition, apparent rigor mortis, dependent lividity, and fixed dilated pupils are not always reliable criteria for withholding CPR in the hypothermic patient. Because intermittent flow may provide adequate support during evacuation, CPR should not be withheld just because continuous compressions cannot be assured.

In a multicenter survey of 428 cases, 9 of the 27 patients receiving CPR initiated in the field survived, as did 6 of 14 patients with CPR initiated in the emergency department. Since then, the literature has corroborated this observation.

The rescuer should initiate CPR in cases of accidental hypothermia unless do-not-resuscitate status is documented and verified, obviously lethal injuries are present, chest wall depression is impossible, signs of life are present, or rescuers are endangered by evacuation delays or altered triage conditions.

**PHARMACOLOGY**

The efficacy of most medications is temperature dependent. Protein binding increases during hypothermia, and liver metabolism is decreased. Overmedication could be required to achieve a therapeutic response, and subsequent toxic levels would develop with rewarming. No medication should be given orally because of decreased gastrointestinal motility; none should be given intramuscularly because of poor absorption from vasoconstricted sites.

**Cardiovascular**

The effects of hypothermia on the autonomic nervous system vary. In primate studies, the sympathetic nervous system responds rapidly to cooling from 37° to 31° C. It then switches off around 29° C, which suggests that modest catecholamine support might be useful below that temperature. In general, pharmacologic manipulation of the pulse and blood pressure should be avoided. Vasoconstrictors may be dysrhythmogenic while having a minimal effect on the maximally constricted peripheral vasculature. Epinephrine and other vasoconstrictors should generally be avoided.

Inotropic agents are not necessary to support the blood pressure. Low-dose (2–5 µg/min) dopamine infusions should be considered in disproportionately hypotensive patients who do not maintain a mean arterial pressure of 60 mm Hg in response to crystalloids, colloids, and rewarming. To facilitate perfusion of a vasoconstricted cardiovascular system while on dopamine, some investigators add an infusion of low-dose nitroglycerin.

**Dysrhythmia Treatment**

Preexisting chronic premature ventricular contractions can be suppressed during hypothermia and recur during rewarming. Most hypothermia-induced dysrhythmias convert spontaneously during rewarming. Asystole that develops during rewarming is not a more ominous rhythm than VF. VF should be defibrillated at 2 W sec/kg up to 200 W sec. A successful reestablishment of electromechanical activity has been reported at 20° C. If the defibrillation attempt is unsuccessful, active rewarming should be initiated with available equipment while CPR is continued. Defibrillation attempts are usually unsuccessful until the core temperature is well above 28° to 30° C. If unsuccessful, the core temperature should be raised above 30° C before further reattempts.

Virtually all atrial dysrhythmias are common below 32° C and are associated with a slow ventricular response. Atrial fibrillation is common and considered innocent. It usually converts spontaneously during rewarming. Digitalization and calcium channel blockade are not warranted.

The ideal approach to ventricular dysrhythmias is unresolved. Lidocaine and propranolol have minimal hemodynamic effects during hypothermia. Their efficacy in treating ventricular dysrhythmias appears limited.

Although no longer available, bretylium tosylate was extremely effective in several animal studies before invasive maneuvers performed after induction of hypothermia. Several clinical chemical defibrillations with bretylium in cases of...
severe hypothermia are reported.27 The prophylactic value of bretylium or lidocaine during hypothermia has not been evaluated. In a canine model of severe hypothermic VF, neither amiodarone nor bretylium was effective.59

In cases of normothermia, group I ventricular antidysrhythmics directly decrease conduction velocity and possess indirect anticholinergic activity. In cases of hypothermia, at least one agent in this group, procainamide, reportedly increases the incidence of VF. Another drug in the group, quinidine, has prevented VF during induced profound hypothermia and during cardiac manipulation at 25° to 30° C.

Transvenous intracardiac pacing is extremely hazardous for hypothermia-induced bradydysrhythmias. External noninvasive pacing by means of large low-resistance electrodes is a successful alternative to emergency transvenous pacing in the rare setting of a profoundly disproportionate bradycardia.60

**Failure to Rewarm**

Cold exposure normally induces adrenal unresponsiveness to adrenocorticotrophic hormone. A false diagnosis of decreased adrenal reserve in hypothermia is possible. The increase in adrenocorticotrophic hormone level seen in hypothermic individuals may be a neurogenic or emotional response to the cold.

Acute cold stress initially stimulates cortisol secretion. The patient may already have a very high level as a result of an underlying stress. In clinical series, serum cortisol levels are commonly elevated. The percentage of cortisol bound to protein is increased with hypothermia, and therefore the active free fraction is decreased.

If a patient fails to rewarm, the historian should search for evidence of adrenocortical insufficiency or steroid dependence. At that juncture, administration of 30 mg/kg methylprednisolone sodium succinate or 250 mg intravenous hydrocortisone should be considered.

Empirical treatment with thyroxine should be reserved for patients thought to be myxedematous. Thyroid hormone replacement is recommended if a history of hypothyroidism is present, a suggestive neck scar is present, or a failure to rewarm occurs. After thyroid function study samples are drawn, 250 to 500 µg of levothyroxine should be administered cautiously intravenously over several minutes. Daily injections of 50 to 100 µg are necessary for 5 to 7 days. Hydrocortisone (100–200 mg) should be added to the first several liters of crystalloid fluid.

The absorption of levothyroxine is variable when it is administered orally or intramuscularly. Administration intravenously results in a smooth effect after the onset of action at 6 to 12 hours. This is evidenced by improvement in the vital signs and the rewarming rate. Half the dose is converted by the peripheral tissues into 1-triiodothyronine (T3). If there is no improvement, 25 µg T3 should also be given every 6 hours through a nasogastric tube.72 An underlying infection also compromises thermogenesis.61 In an urban setting, infection is the leading cause of failure to rewarm and of mortality.

**Septicemia**

Hypothermia compromises host defenses and predisposes to infection. The usual signs of infection, including fever, are absent. Shaking chills from sepsis may be mistaken for shivering. If a patient’s mental status remains altered despite rewarming, CNS injury or infection should be suspected.

Diminished bone marrow release and circulation of neutrophils, along with impaired neutrophil migration and bacterial phagocytosis, are factors contributing to infection. In children younger than 3 months, prophylactic antibiotics after culturing are indicated. No reliable clinical or laboratory indicators of infection exist, but bradycardia, anemia, uremia, and serum glucose levels, as well as leukocyte abnormalities, are common clues.

The role of antibiotic prophylaxis in adults is less clear. Although gram-negative septicemia may be the cause of hypothermia, coexistent infections from gram-positive cocci, enterobacteriaceae, and oral anaerobes are common.

Elderly patients with thermoregulatory failure have a high risk of mortality and should be considered septic until proven otherwise. Routine antibiotic prophylaxis in hypothermic adults, unlike in elderly patients and in children, does not appear warranted. Antibiotics should be administered if the clinical picture is consistent with septic shock, if there is failure to rewarm, or if aspiration has occurred. Cellulitis, myositis, bacteriuria, or infiltrates present on chest radiographs all warrant immediate antimicrobial therapy.12

**REWARMING**

Since no controlled studies comparing rewarming methods in hypothermia exist, rigid treatment protocols would not be evidence based.40,62–64 As a result, the clinician should consider the advantages, disadvantages, indications, contraindications, and specific guidelines for the various reported techniques of rewarming that follow.

**Passive External Rewarming**

Spontaneous passive external rewarming is noninvasive and is the treatment of choice for most patients with mild hypothermia. During passive external rewarming, the patient must be able to metabolically generate sufficient heat to maintain an acceptable rate of spontaneous rewarming. Elderly patients are commonly glycogen depleted, centrally hypovolemic, and not capable of normal cardiovascular or metabolic homeostasis.

The normal processes of heat dissipation are minimized by passive external rewarming. Cessation of vaporization and convection are coupled with insulation against further radiation of heat. This technique simply involves covering the patient with an insulating material in a favorable atmospheric condition. The ambient temperature should exceed 21° C. When the air is stationary, less heat is lost to conduction, convection, and radiation.

Below 30° C, humans are functionally poikilothermic. No shivering thermogenesis occurs. Shivering is the thermoregulatory neuromuscular response to cold that increases heat production from 250 to 1000 kcal/hr. Without it, the endogenously generated metabolic heat is insufficient to raise the core temperature. When the core temperature exceeds 32° C, the major source of heat production is shivering thermogenesis, unless complete glycogen depletion occurs.

Recommended rewarming rates vary between 0.5° and 2.0° C/hr. The rewarming rate should be rapid enough to avoid prolonged exposure to dysrhythmias.

**Active Rewarming**

Active rewarming is the direct transfer of exogenous heat to the patient. It can be accomplished by either external or internal techniques.

Cardiovascular instability and decompensation require rapid elevation of the core temperature (Box 138-3). Defibrillation is rarely successful at temperatures below 28° to 30° C. Active rewarming is indicated in patients with cerebrovascular accidents and other conditions that impair CNS control of
thermoregulation. Active rewarming is also indicated in patients when endogenous thermogenesis is insufficient or when glycogen depletion is present. These diseases are usually endocrinologic and include hypopituitarism, adrenal insufficiency, hypothyroidism, and Wernicke’s encephalopathy. Active rewarming is also indicated if diabetic ketoacidosis is present because the core temperature must be elevated well above 30°C before insulin becomes effective.65

Pharmacologically induced peripheral vasodilation or acute spinal cord transection renders a patient incapable of sufficient thermogenesis, and such patients should be actively warmed. Active rewarming in patients with moderate or severe hypothermia is also indicated because of the potential for cardiovascular decompensation or ventricular irritability. Patients with severe hypothermia and a sustained perfusing rhythm do not necessarily require invasive extracorporeal rewarming techniques.66

Aggressive treatment of hypothermia in infants is also indicated. Rapid rewarming may be advantageous because it minimizes energy expenditures.57 Vigorous monitoring for infectious, respiratory, hematologic, and metabolic complications is needed.

### Active External Rewarming

Early concern with active external rewarming (AER) was voiced by Duguid and colleagues68 in 1961, when 20 of their 23 patients died. Retrospective analysis of numerous clinical series notes widely varying mortality rates with AER.7,17,65

Various methods are available to conduct heat directly to the skin. Immersion in a bath of 40°C is one option. Disadvantages of this approach include the inability to monitor or resuscitate the patient in water and the difficulty of performing CPR on a floating body.

Other rewarming options include plumbed garments that recirculate warm fluids, hot water bottles, heating pads, forced-air warming systems, and radiant sources. Thermal injury to vasoconstricted hypoperfused skin is a common hazard with local heat application.69

Forced air warming systems efficiently transfer heat.70-73 The Bair Hugger® circulates hot air through a “blanket.” The air exits apertures on the patient side of the cover, which allows a convective transfer of heat. In one study in which accidental hypothermia victims were warmed in the emergency department, rewarming shock and core temperature afterdrop were not noted.74 Both groups of patients were also treated with heated inhalation and warmed intravenous fluids. The use of forced-air warming systems is currently most practical in the emergency department.74-76 Although these devices decrease shivering thermogenesis, afterdrop is minimized and heat transfer can be significant.

Arteriovenous anastomoses rewarming is another noninvasive AER technique first described by Vangaard in 1979.77 Exogenous heat is provided by immersion of the lower parts of the extremities (hands, forearms, feet, calves) in 44° to 45°C water. The heat opens the arteriovenous anastomoses (AVAs). These organs are 1 mm below the epidermal surface in the digits.78 As a result, there is an increased flow of warmed venous subcutaneous blood returning directly to the heart.

A permutation of AVA rewarming is negative pressure rewarming. Under hypothermic conditions, the AVAs remain closed during peripheral vasoconstriction. In combination with localized heat application, the application of subatmospheric pressure distends the venous rete and increases flow through the AVAs.

To initiate negative pressure rewarming, the forearm is inserted through an acrylic tubing sleeve device fitted with a neoprene collar. This allows an airtight seal to form around the forearm. After a 40 mm Hg vacuum pressure is created, heat is applied over the dilated AVAs.79 The clinical practicality and efficacy of AVA rewarming is unclear.

Optimal candidates for AER are previously healthy patients with acute hypothermia. In these patients, minimal dehydration and pathophysiologic circulatory changes have occurred.80 If AER is chosen and the extremities are vasoconstricted, the heat source should generally be applied only to the thorax. Application of heat to the extremities increases the cardiovascular load by increasing the metabolic requirements of the peripheral musculature. The depressed cardiovascular system may not be able to meet the demands, and cardiovascular collapse can occur.

Combining truncal AER with core rewarming is also successful. Some researchers believe that providing heated humidified oxygen and warmed intravenous fluids in addition to AER may anticipate and avert hypoxia, metabolic acidosis, core temperature afterdrop, and hypotension. If AER is chosen as the method of treatment for moderate or severe hypothermia, it should be combined with one of the active core rewarming techniques.

### Active Core Rewarming

Numerous alternatives have been explored to achieve active rewarming of the core. These techniques minimize rewarming collapse in patients with temperatures below 32°C.

#### Airway Rewarming

Airway rewarming as an adjunctive active core rewarming technique has been explored in research laboratories and clinically since first suggested by Lloyd.25 This simple technique is indicated in all cases of moderate or severe hypothermia.81

Advantages of heated humidified oxygen include noninvasiveness, cost, simplicity, assurance of adequate oxygenation, and avoidance of afterdrop. Additional benefits are the stimulation of pulmonary cilia, a decrease in pulmonary secretion viscosity, and a reduction of cold-induced bronchorrhea. Pulmonary absorption occurs without adverse effects on surfactant or increased pulmonary congestion.

The respiratory tract is a limited site for heat exchange.46 Nevertheless, both the oxygen content and the temperature in the pulmonary vasculature rise. The myocardium is perfused by warmer oxygenated blood, stabilizing against intermittent temperature gradients.

A sufficient respiratory minute volume and complete humidification are necessary for maximal heat delivery. Because of the low thermal conductivity of dry air, ventilation with warm dry air provides negligible heat. Depending on the technique used (endotracheal tube more than mask), one should expect a rewarming rate between 1° and 2.5°C/hr.317

Heated mask ventilation is also of interest. A thermal countercurrent heat exchanger exists in the cerebrovascular bed of humans. This system, known as the rete mirabile, could preferentially rewarm the brainstem. Another option is heated inhalation through face mask continuous positive airway pressure.
Maintenance of sufficient oxygenation is also critical in moderate and severe cases. Fisher considered the effects of hypothermia, pH, Paco₂, and the level of 2,3-diphosphoglycerate on the shift of the oxyhemoglobin dissociation curve. In patients on cardiopulmonary bypass cooled to 28° to 30°C, the capacity of hemoglobin to unload oxygen to the tissue is less than half that found in normothermic patients.82 Despite lower metabolic requirements, this decrease in "functional" hemoglobin, combined with a depressed respiratory minute volume, results in minimum oxygen reserves.

Some patients maintain a level of spontaneous respiration appropriate to the depressed carbon dioxide production. This is not the case in patients with coexisting toxicologic, traumatic, or metabolic depression of their respiratory centers. During spontaneous or assisted ventilation with heated ventilation, there is the flexibility to alter the fraction of inspired oxygen (Fio₂), monitor airway pressure, and deliver continuous positive airway pressure or positive end-expiratory pressure.

The technique for patients with spontaneous respirations requires a heated cascade nebulizer. An immersion heater can be connected to a hose with a warming wire. Because patients with a depressed level of consciousness do not complain of pain, it is essential to frequently check the temperature of the inspired air with an in-line temperature probe. The gas temperature should be maintained at 42° to 45°C. Most heater modules require modification to allow the temperature to reach 42° to 45°C and should be so labeled to avoid routine use.

Most humidifiers are manufactured in accordance with the International Standards regulations. The humidifier does not exceed 41°C close to the patient outlet with a 6-foot tubing length.

Strategies to circumvent the 41°C ceiling include reduction of tubing length, adding more heat sources, disabling the humidifier safety system, and placing the temperature probe outside the patient circuit.83 Due to the modest clinical benefit in stable patients, circumventing the 41°C ceiling may not be worth the effort. The only report of thermal airway injury is outside the patient circuit.83 Due to the modest clinical benefit in stable patients, circumventing the 41°C ceiling may not be worth the effort. The only report of thermal airway injury is outside the patient circuit.83 Due to the modest clinical benefit in stable patients, circumventing the 41°C ceiling may not be worth the effort. The only report of thermal airway injury is outside the patient circuit.83 Due to the modest clinical benefit in stable patients, circumventing the 41°C ceiling may not be worth the effort.

Complete airway protection averts aspiration. Hypothermia is associated with ileus, bronchopneumonia, and depressed protective airway reflexes. Although the airway rewarming technique provides less heat than other forms of active core rewarming, it is safe, noninvasive, and practical.

**Peritoneal Dialysis.** This technique delivers dialysate at 40° to 45°C to the peritoneal cavity. Heat is conducted directly to the posterior parietal peritoneum to the solid viscera and through the hemidiaphragms to the heart and lungs. A double-catheter system can increase the rate of rewarming with suction at the outflow. The usual clinically attainable rate is 6 L/hr. Two liters are infused, retained for 20 minutes, and then aspirated. Rewarming rates average 1° to 3°C/hr, depending on gradients and flow rates and dwell times.

An additional benefit of this invasive technique is hepatic rewarming, which reactivates depressed detoxification and conversion enzymes. Peritoneal dialysis can exacerbate preexisting hypokalemia; therefore, serum electrolytes should be carefully monitored. Peritoneal lavage rewarming should not be selected routinely for stable patients. It should be considered in severe cases and in combination with all available rewarming techniques for patients without spontaneous perfusion.89

**Heated Irrigation.** Heat transfer from irrigation fluids is usually very limited because the surface area available for heat exchange is minimal. Gastric or colonic irrigation can cause fluid and electrolyte fluxes. Exceeding 200- to 300-mL aliquots may force fluid into the duodenum; therefore, frequent fluid removal via gravity drainage minimizes “lost” fluid. A log of input and output is essential. A double-lumen esophageal tube and other modified Sengstaken tubes have been used.84

Closed thoracic lavage in accidental hypothermia is another option.44,85,86 Two large-bore thoracostomy tubes are inserted into one or both hemithoraces. One is inserted anteriorly in the second or third intercostal space at the midclavicular line. The other is inserted between the fifth and sixth intercostal space in the posterior axillary line. Normal saline solution is heated to 40° to 42°C and sterilized infused into either tube and drained.87 The dwell time for thermal transfer will be longest if the fluid is infused into the inferior tube. One should leave the inferior tube for drainage after rewarming.

The efficiency of heat transfer varies with the flow rate and dwell times. Pleural adhesions prevent adequate infusion rates and can result in a tension hydrothorax. Adequate drainage must be ensured to prevent intrathoracic hypertension.

Thoracic lavage should be reserved for the severely hypothermic patient who does not respond to standard techniques or the patient with another indication for a chest tube. It should be combined with all other available rewarming modalities in potentially salvageable cardiac arrest patients.53,88,89

The rate of rewarming averages 3° C/hour.86 Mediastinal irrigation and direct myocardial lavage should only be considered in patients without spontaneous perfusion. The procedure requires a standard left lateral thoracotomy incision. The pericardium is not incised unless an effusion or tamponade is present. The heart is bathed in 1 to 2 L of an isotonic solution heated to 40°C for several minutes. The fluid is then removed and the lavage repeated. Internal defibrillation is attempted at 2°C intervals after the myocardial temperature exceeds 26° to 28°C. When a perfusing rhythm is achieved, lavage is continued until the myocardial temperature exceeds 32°C. A median sternotomy approach allows ventricular decompression in addition to direct defibrillation. Open cardiac massage of a cold, rigid, and contracted heart may not generate flow.49,51

**Diathermy.** Truncal diathermy may soon prove clinically useful. Diathermy involves the conversion of energy waves into heat. Large amounts of heat can be delivered to deep tissues with ultrasonic and low-frequency microwave radiation. Frostbite, burns, significant edema, and the presence of all types of metallic implants and pacemakers contraindicate diathermy.

Regional heating of hypothermic dogs after immersion does not damage tissue at 4 to 6 W/kg and rapidly elevates the core temperature. Zhong and associates80 rewarmed 16 piglets with microwave irradiation "until they squealed and sucked." In a subsequent experiment, 20 of 28 human infants were successfully rewarmed with microwave irradiation at 90 to 100 W. **Extracorporeal Blood Rewarming.** The four common techniques to rearm blood are venovenous rewarming, hemodialysis, continuous arteriovenous rewarming, and cardiopulmonary bypass (CPB) (Table 138-2).90-92

Extracorporeal venovenous rewarming is an option for warming and recirculating the blood. With this technique, blood is removed, usually by a central venous catheter, heated to 40°C, and returned via a second central or large peripheral venous catheter. Flow rates of 150 to 400 mL/min have been achieved.93,94

The circuit is not complex and is more efficient than many other nonbypass modalities. There is no oxygenator, and since...

CAVR, continuous arteriovenous rewarming; CPB, cardiopulmonary bypass; CV, central venous; ROR, rate of rewarming.

Lastly, cardiopulmonary bypass utilizes the standard femoral-femoral circuit and includes arterial and venous catheters, a mechanical pump, a membrane or bubble oxygenator, and a heat exchanger. A 16 to 30F venous cannula is inserted via the femoral vein to the right atrium/inferior vena cava junction. The tip of the shorter 16 to 20F arterial cannula is inserted 5 cm or just proximal to the aortic bifurcation. Transesophageal echocardiography can help evaluate ventricular load and valve function.

There are techniques to decrease the need for intravenous anticoagulation that previously limited clinical applicability. Heparin-coated perfusion equipment and the use of non-thrombogenic pumps can be coupled with the enhanced physiologic fibrinolysis seen in the first hour of CPB.

Heated, oxygenated blood is returned via the femoral artery. Femoral flow rates of 2 to 3 L/min can elevate the core temperature 1° to 2°C every 3 to 5 minutes. In Splittgerber’s review the mean CPB temperature increase was 9.5°C/hr. Most pumps can generate full flow rates up to 7 L/min.

The optimal temperature gradient and bypass rewarming rates are unknown. An excessive temperature gradient between brain tissue and circulant can adversely affect electroencephalographic regeneration. The other concern is the possibility of increased bubbling if high perfusate temperature gradients are used. Most investigators use 5° to 10°C gradients.

The major advantage of CPB in perfusing patients is the preservation of flow if mechanical cardiac activity is lost during rewarming. Other candidates for CPB are patients who do not respond to less invasive rewarming techniques, those with completely frozen extremities, and those with rhabdomyolysis accompanied by major electrolyte disturbances.

Of note, rapid acceleration of the rate of rewarming does not necessarily improve survival rates. Complications of rapid rewarming in severe hypothermia include disseminated intravascular coagulation, pulmonary edema, hemolysis, and acute tubular necrosis.

Extracorporeal blood rewarming should be attempted in hypothermic cardiac arrest patients when no contraindications to CPR exist. A realistic assessment of the risk-to-benefit ratio for debilitated patients with secondary hypothermia should be made. The lowest temperature in a survivor of induced hypothermia was 9°C. Extracorporeal blood rewarming is unlikely to succeed below 5°C. Resuscitation should be discontinued if frozen or clotted intravascular contents are identified.

DISPOSITION

Otherwise healthy patients who have mild primary accidental hypothermia (35-32.2°C) usually warm easily in the emergency department. They can be safely discharged if a warm environment is available.

Patients with more severe hypothermia (<32.2°C) almost always require admission. These patients should be evaluated for the presence of underlying medical disorders (see Box 138-1). Cardiac monitoring should be considered in patients with persistent toxicologic or metabolic abnormalities. This is essential for those patients displaying cardiovascular instability or an inadequate rate of rewarming. Transferring patients to tertiary care centers is generally not necessary; however, some severely hypothermic patients are best managed in facilities with CPB capabilities.

OUTCOME

In the past, the treatment dictum was that “no one is dead until they are warm and dead.” Some patients are cold and dead, and it would be useful and humane if they could be
safely identified. Because of the variability of human physiologic responses, outcome is difficult to predict. The type and severity of the underlying or precipitating disease process are the major determinants. Patient age is not an independent predictor of mortality.

Trauma, infection, and toxin ingestions also affect survival unpredictably. Outcome prediction based on the Glasgow Coma Scale score is unreliable. Further refinement of a hypothermia outcome score developed from a large database may enable multiple observers at different sites to assess treatment modalities and outcome predictors. Significant predictors of outcome include asphyxia, prehospital cardiac arrest, a low or absent blood pressure, elevated BUN level, and the need for either endotracheal or nasogastric intubation in the emergency department.

The search for a valid triage marker of death continues. Grave prognostic indicators include evidence of intravascular thrombosis (fibrinogen <50 mg/dL), cell lysis (hyperkalemia >10 mEq/L), and ammonia levels greater than 250 mmol/L. These indicators have not been prospectively validated.

KEY CONCEPTS

- Indications for active rather than passive rewarming include cardiovascular instability, temperature below 32°C, poor rate of rewarming, endocrinologic insufficiency, and vasodilation.
- One should consider hypoglycemia, hypovolemia, or an overdose if there is a tachycardia disproportionate to the temperature.
- The efficacy of most medications is temperature dependent. Overmedication to achieve an effect when the patient is cold could cause toxicity during rewarming.
- Kinetic laboratory tests of coagulation are performed at 37°C. Despite a clinically obvious coagulopathy, the values will be deceptively “normal.”
- There are no safe predictors of serum electrolytes. Hypothermia enhances the cardiac toxicity of hyperkalemia and obscures premonitory electrocardiographic changes.
- Failure to rewarm despite good technique should suggest infection, endocrinologic insufficiency, or a futile resuscitation.

**PERSPECTIVE**

Humans have been plagued by heat illness throughout recorded history, often as the result of military exercises, athletic events, or recreational activities. The ancient Greeks named a disease that resembled heatstroke *siriasis* after the dog star Sirius, which accompanies the summer sun. The U.S. Army reported at least 125 deaths from heatstroke during basic training in the years 1941 to 1944. Modern military organizations continue to encounter heat illness because of the requirement to train unacclimatized troops with forced heavy physical exercise. Furthermore, athletes are also prone to heat illness. Between 1961 and 1971, 46 U.S. football players died of heatstroke. Heatstroke was once third only to head and spinal cord injuries and cardiac arrest as a cause of death among U.S. athletes. When environmental heat stress is maximal, strenuous exercise is not required to produce heat illness.

The elderly and poor, often lacking adequate air-conditioning and nutrition, and those with preexisting disease are prone to heat illness during environmental extremes. In heat wave years in the United States, approximately 10 times as many deaths are reported as during non–heat wave years. It is also estimated that at least 10 times as many heat-aggravated illnesses occur because of myocardial infarction, cerebrovascular accident, and other causes. More than 700 excess deaths were caused by the heat during the 1995 heat wave in Chicago. The heat wave during the summer of 2003 is estimated to have caused 14,800 deaths in France, and climate models suggest an increase in both frequency and intensity of heat waves in temperate areas in the future.

**PRINCIPLES OF DISEASE**

**Physiology of Heat**

**Heat Production**

Humans can be considered biochemical “furnaces” that burn food to fuel a complex array of metabolic functions. These chemical reactions consume substrate, generate usable energy, and produce by-products that must be eliminated for continued operation of the system. Water and carbon dioxide are produced and eliminated in large quantities, as are urea, sulfates, phosphates, and other chemical products. All of these reactions are exothermic and combine to produce a basal metabolic rate that amounts to approximately 100 kcal for a 70-kg person. In the absence of cooling mechanisms, this baseline metabolic activity would result in a 1.1°C hourly rise in body temperature.

Heat production can be increased up to 20-fold by strenuous exertion. Rectal temperatures as high as 42°C are recorded without ill effects in trained marathon runners. Metabolic factors, such as hyperthyroidism or sympathomimetic drug ingestion, can dramatically increase heat production. Environmental heat not only adds to the heat load but also interferes with heat dissipation. The physics of heat transfer as it relates to human physiology involves four mechanisms: conduction, convection, radiation, and evaporation.

**Conduction**

Conduction is the transfer of heat energy from warmer to cooler objects by direct physical contact. Air is a good insulator; therefore, only approximately 2% of the body heat loss is by conduction. In contrast, the thermal conductivity of water is at least 25 times that of air.

**Convection**

Heat loss to air and water vapor molecules circulating around the body is termed convection. As ambient temperature rises, the amount of heat dissipated by convection becomes minimal, and once air temperature exceeds the mean skin temperature, heat is gained by the body. Convective heat loss varies directly with wind velocity. Loose-fitting clothing maximizes convective (and also evaporative) heat loss.

**Radiation**

Radiation is heat transfer by electromagnetic waves. Although radiation accounts for approximately 65% of heat loss in cool environments, it is a major source of heat gain in hot climates. Up to 300 kcal/hr can be gained from radiation when a person is directly exposed to the hot summer sun.

**Evaporation**

Evaporation is the conversion of a liquid to the gaseous phase. Evaporation of 1 mL of sweat from the skin cools the body by 0.58 kcal. As ambient temperature rises, evaporation becomes the dominant mechanism of heat loss. Panting mammals such
Heat Regulation

The regulation of body temperature involves three distinct functions: thermosensors, a central integrative area, and thermoregulatory effectors.

Thermosensors. Temperature-sensitive structures are located both peripherally in the skin and centrally in the body. Skin temperature changes, however, correlate poorly with changes in the rate of heat loss. Thermosensitive neurons are in the preoptic anterior hypothalamus. They are activated when the temperature of the blood circulating through that area exceeds a “set point.”

The skin temperature affects heat loss, since a person resting in a warm environment initiates sweating, even though the core temperature remains constant. In contrast, changes in core temperature are more potent in producing heat-dissipating responses than skin temperature changes.

Central Integrative Area. The central nervous system (CNS) interprets information received from the thermosensors to properly instruct thermoregulatory effectors. The concept of a central thermostat by which an alteration shifts effector thresholds in the same direction fits a variety of clinical situations. For example, fever, the circadian rhythm of temperature variation, and the 0.5°C difference in rectal temperature after ovulation can be explained by variation of a thermal set point.

Thermoregulatory Effectors. Sweating and peripheral vasodilation are the major mechanisms by which heat loss can be accelerated. In a warm environment, evaporation of sweat from the skin is the most important mechanism of heat dissipation. Heat loss from the skin by convection and radiation is maximized by increased skin blood flow to facilitate sweating.

Humans possess apocrine and eccrine sweat glands. Apocrine glands are concentrated in the axillae and produce milky sweat rich in carbohydrate and protein. They are adrenergically innervated and respond to emotional stress as well as to heat. Most glands producing “thermal sweat” are eccrine glands. These are cholinergically innervated and distributed over the entire body, with the largest number on the palms and soles. Eccrine sweat is colorless, odorless, and devoid of protein. Individuals exercising in hot environments commonly lose 1 or 2 L/hr of sweat; loss of 4 L/hr for short periods is possible.

Cooling is best achieved by evaporation from the body surface; sweat that drips from the skin does not cool the body, and sweat evaporated from clothing is considerably less efficient. Each liter of completely evaporated sweat consumes 580 kcal of heat. The ability of the environment to evaporate sweat is termed atmospheric cooling power and varies primarily with humidity but also with wind velocity. As humidity approaches 100%, evaporative heat loss ceases.

The vascular response to heat stress is cutaneous vasodilation and compensatory vasoconstriction of splanchnic and renal beds. These vascular changes are under neurogenic control and allow heat to be dissipated quickly and efficiently, but they place a tremendous burden on the heart. To maintain blood pressure, cardiac output must increase dramatically. For this reason, saunas and hot tubs may be dangerous for patients with cardiac disease. Cardiovascular and baroreceptor reflexes also affect skin blood flow. Reduced forearm sweating and vasodilation are observed in severely dehydrated subjects exercising in a warm environment.

Acclimatization. Acclimatization is defined as “a constellation of physiologic adaptations that appear in a normal person as the result of repeated exposures to heat stress.” Daily exposure to work and heat for 100 min/day results in near-maximal acclimatization in 7 to 14 days. This is characterized by an earlier onset of sweating (at a lower core temperature), increased sweat volume, and lowered sweat electrolyte concentration. Acclimatization is hastened by modest salt deprivation and delayed by high dietary salt intake. As acclimatization proceeds, the sweat sodium concentration decreases while the volume increases.

The cardiovascular system plays a major role in both acclimatization and endurance training, largely resulting from an expansion of plasma volume. Heart rate is lower and associated with a higher stroke volume. Other physiologic changes include earlier release of aldosterone, although acclimatized individuals generate lower plasma levels of aldosterone during exercise heat stress. Total body potassium depletion of up to 20% (500 mEq) by the second week of acclimatization can occur as a result of sweat and urine losses coupled with inadequate repletion.

Although many similarities exist between thermoregulatory responses to heat and exercise, the well-conditioned athlete is not necessarily heat acclimatized. To maintain heat and exercise-induced adaptive responses, heat exposure needs to continue intermittently at least on 4-day intervals. Plasma volume decreases considerably within 1 week in the absence of heat stress.

PATHOPHYSIOLOGY

Predisposing Factors for Heat Illness

Elderly patients, psychiatric patients, or those with chronic diseases who are taking medications predisposing to heat illness are prone to classic heatstroke during periods of high ambient heat and humidity. Adequate fluid intake is essential. Elderly patients sometimes dress inappropriately for hot weather; heat loss is maximized by light, loose-fitting garments.

Exertional heatstroke is most likely to occur in young, healthy people involved in strenuous physical activity, especially if they have not acclimatized to environmental factors that overwhelm heat-dissipating mechanisms. Fluid intake is the most critical variable. Dehydration can be minimized by education on work-rest cycles and fluid consumption and through provision of cool, pleasantly flavored fluids.

The goal is to maximize voluntary fluid intake and gastric emptying so that fluid can rapidly enter the small intestine, where it is absorbed. Gastric emptying is accelerated to 25 mL/min by large fluid volumes (500–600 mL) and cool temperatures (10–15.8°C). High osmolality inhibits gastric emptying; osmolality of less than 200 mOsm/L is optimal. Most commercially available electrolyte solutions contain excessive sugar. Hydration can be monitored by measuring body weight before and after training or athletic competition. An athlete with a loss of 2 or 3% body weight (1.5–2 L in a 70-kg man) should drink extra fluid and be permitted to compete only when within 0.5 to 1 kg (1 or 2 pounds) of the starting weight on the previous day. A weight loss of 5 or 6% represents a moderately severe deficit and usually is associated with intense thirst, scanty urine, tachycardia, and an increase in rectal temperature of approximately 2°C. Such athletes should be restricted to light workouts after hydration until they return to normal weight. A loss of 7% or more of body weight represents severe water depletion; the athlete should not participate in sports until examined by a physician.
Wet Bulb Globe temperature

**PART IV**

**Environment**

1884

Caused by gastroenteritis, diuretics, or inadequate fluid. Taking beta-adrenergic blocking agents may be unable to increase their cardiac output sufficiently to produce the necessary peripheral vasodilation to dissipate heat. Dehydration increases body temperature at rest by increasing the work of the sodium-potassium adenosine triphosphatase pump, which accounts for 25 to 45% of basal metabolic rate. This is particularly true in cases of hypernatremic dehydration. The pipes and valves of the coolant system may be abnormal in diabetic or elderly patients with extensive atherosclerosis.

Effective circulation requires both an intact pump and adequate coolant levels. Individuals with cardiac disease or those taking beta-adrenergic blocking agents may be unable to increase their cardiac output sufficiently to produce the necessary peripheral vasodilation to dissipate heat. Dehydration caused by gastroenteritis, diuretics, or inadequate fluid intake predisposes to heat illness. Individuals working in the interiors of automobiles, tanks, and tents in the sun, as well as engine rooms, hot tubs, and saunas. Children are more susceptible to heat stressors because of abuse interfere with sweating and produce heat illness. Various skin diseases, including miliaria (prickly heat rash), extensive burns, scleroderma, ectodermal dysplasia, and cystic fibrosis, are all risk factors. Anhidrosis can be secondary to either central or peripheral nervous system disorders as well.

The heat strain index is widely accepted as an example of an index that includes environmental and physiologic factors. There are several variations and modified heat strain indexes in existence, with varying ease of use and accuracy (Fig. 139-2). Before the advent of air-conditioning, mortality increased threefold to fivefold in nursing homes and threefold in the general population during heat waves. Mortality in geriatric patients correlates with average weekly peak air temperature. Most deaths in the 2003 European heat wave occurred in elderly patients. Microclimates conducive to heat illness are produced in the interiors of automobiles, tanks, and tents in the sun, as well as engine rooms, hot tubs, and saunas. Children are more susceptible to heat stressors because of abuse interfere with sweating and produce heat illness. These measurements can be done manually or automatically calculated with the help of computer algorithms.

The wet bulb globe temperature heat index is an excellent meteorological measure of environmental heat stress (Box 139-1). It includes the effects of temperature, humidity, and radiant thermal energy from the sun. When climatic conditions exceed 25°C wet bulb, even healthy people are at high risk if they choose to exercise. Above 28°C, exercise and strenuous work should be avoided or limited to extremely short periods.

increase in mortality from cocaine overdose. Many younger patients who die from hyperthermia test positive for cocaine. There are also reports of heatstroke occurring in well-trained military soldiers or athletes who ingest dietary supplements containing ephedrine.

Certain patients undergoing general anesthesia rapidly experience severe hyperthermia, muscular rigidity, and acidosis. This syndrome, termed malignant hyperthermia, is the result of a genetically determined instability of skeletal muscle sarcoplasmic reticulum that allows inappropriate intracellular calcium release. Dantrolene, which lowers myoplasmic calcium, is effective in the prevention and treatment of this syndrome.

Malignant hyperthermia is rarely seen in outpatient settings, but a clinically similar entity, neuroleptic malignant syndrome, is often encountered. This syndrome is induced by antipsychotic medications and is characterized by muscular rigidity, severe dyskinesia or akinesia, hyperthermia, tachycardia, dyspnea, dysphagia, and urinary incontinence. Although the lead-pipe rigidity and hyperthermia are reminiscent of malignant hyperthermia, the putative mechanism is different. Dopamine receptor blockade in the corpus striatum caused by haloperidol and similar agents produces severe muscle spasticity and dis-
able begins to feel cold and chooses a warmer environment. This behavioral drive is coordinated with the autonomic mechanisms such as shivering to increase body temperature to the new set point. In most circumstances, temperature elevation is not a significant problem, and therapy is directed at the underlying disease state. Fever does not cause primary pathologic or physiologic damage to humans and does not require primary emphasis in the therapeutic regimen, which is directed at the underlying disease state. However, if temperature-related physiologic changes such as febrile seizures or tachycardia in a patient with marginal cardiac reserve compromise the individual, temperature must be artificially regulated.

Since fever is the product of a molecular interaction that establishes a new physiologic thermal set point, therapeutic attempts to lower temperature are opposed by body mechanisms that attempt to maintain the new set point. Thus, attempts at whole-body cooling produce violent shivering and discomfort. The use of agents to block the causative molecular interaction is the most clinically effective approach. Aspirin and other antipyretics block the action of the pyrogen at hypothalamic receptor sites through inhibition of prostaglandin synthesis. These antipyretics are not effective against and should not be used to control environmental hyperthermia.

MINOR HEAT ILLNESS

Heat Cramps

Physiology

Heat cramps are brief, intermittent, and often severe muscular cramps occurring typically in muscles that are fatigued by heavy work. Heat cramps appear to be related to a salt deficiency. Heat cramps occur most commonly during the first days of work in a hot environment and develop in persons who produce large amounts of thermal sweat and subsequently drink copious amounts of hypotonic fluid.

Clinical Factors

Athletes, roofers, steel workers, coal miners, field workers, and boiler operators are among the most commonly reported victims of heat cramps. Heat cramps tend to occur after exercise when the victim has stopped working and is relaxing. In this respect, they differ from the cramps experienced by athletes during exercise, which tend to last for several minutes, are relieved by massage, and resolve spontaneously.

Heat cramps are occasionally confused with hyperventilation tetany, which can occur during heat exhaustion. The latter syndrome can be distinguished by the presence of carpopedal spasm and paresthesias in the distal extremities and perioral area. If accompanied by systemic symptoms, heat cramps may be part of salt-depletion heat exhaustion. Heat cramp victims exhibit hyponatremia, hypochloremia, and low serum sodium and chloride levels. Rhabdomyolysis or resultant renal damage is not present with isolated heat cramps.

Management

Heat cramps are usually rapidly relieved by salt solutions. Commercially available flavored electrolyte solutions are commonly ingested. Mild cases without concurrent dehydration are treated orally with 0.1 or 0.2% salt solution (two to four 10-grain salt tablets [56–112 mEq] or one fourth to one half teaspoon table salt dissolved in a quart of water), which is the general limit of palatability. Severe cases respond rapidly to intravenous isotonic solution (0.9% NaCl). Salt tablets are gastric irritants, delay gastric emptying, and are not recommended.

Heat Edema

Physiology and Clinical Features

Swollen feet and ankles are often reported by nonacclimatized individuals, especially the elderly, who encounter climatic stresses of tropical and semitropical areas. Such individuals often have no underlying cardiac, hepatic, venous, or lymphatic disease. They commonly have assumed rigorous schedules with long periods of sitting or standing. The edema is usually minimal, not accompanied by any significant impairment in function, and often resolves after several days of acclimatization.

It is presumed that hydrostatic pressure and vasodilation of cutaneous vessels, combined with some degree of orthostatic pooling, lead to vascular leak and accumulation of interstitial fluid in the lower extremities. Simultaneously, aldosterone increases in response to the heat stress and perceived central volume deficit.

Awareness of this clinical presentation prevents overly vigorous diagnostic and therapeutic intervention. Brief diagnostic evaluation to rule out thrombophlebitis, lymphedema, or congestive heart failure is appropriate, but invasive diagnostic techniques or vigorous pharmacologic therapy is not indicated.

Management

No evidence exists that diuretic therapy is effective. Rather, simple leg elevation or thigh-high support hose should be used. In most individuals, the problem resolves either through adequate acclimatization or with the individual’s return to a home climate.

Heat Syncope

Physiology and Clinical Features

Heat syncope is a perplexing disorder in which a host of serious and an even larger number of nonserious underlying mechanisms can also result in temporary loss of consciousness. The elderly have a special predilection for this disorder. Individuals adapt to a hot, humid environment by dilation of cutaneous vessels to deliver heat to the body surface. Thus, an increased portion of the intravascular pool is located in the periphery at any given time. Increasing blood flow to compliant cutaneous veins raises skin vascular volume at the expense of thoracic blood volume. Individuals who stand for protracted periods tend to pool blood in the lower extremities. Combined with volume loss and peripheral vasodilation, this pooling can result in inadequate central venous return, a concomitant drop in cardiac output, and cerebral perfusion inadequate to maintain consciousness.

The disorder is self-limited because assumption of a horizontal position is curative. Individuals at risk for heat syncope should be warned to move often, flex leg muscles repeatedly when standing stationary, avoid protracted standing in hot environments, and assume a sitting or horizontal position when prodromal warning symptoms or signs occur. These include scintillating scotomata, tunnel vision, vertigo, nausea, diaphoresis, and weakness.

Prickly Heat

Physiology and Clinical Features

Prickly heat, also known as miliaria rubra, lichen tropicus, and heat rash, is an acute inflammatory disorder of the skin that occurs in tropical climates. It is the result of blockage of sweat gland pores by macerated stratum corneum and secondary staphylococcal infection. The acute phase is characterized by vesicles in the malpighian layer of the skin caused by dilation and rupture of the obstructed sweat gland ducts.

Clinically, this initially produces intensely pruritic vesicles on an erythematous base. The rash is confined to clothed areas, and the affected area is often completely anhidrotic. During approximately the next week, a keratin plug arises and fills these vesicles, causing a deeper obstruction of the sweat gland duct. The obstructed duct then ruptures a second time, producing a deeper vesicle within the dermis. This is known as the profunda stage, and it can persist for weeks. Profunda vesicles are not pruritic and closely resemble the white papules of piloerection; chronic dermatitis is a common complication.

Management

Chlorhexidine in a light cream or lotion is the antibacterial treatment of choice during the acute phase. Salicylic acid, 1%, can be applied three times daily to localized, affected areas to assist in desquamation, but it should not be used in children or over large areas because of possible salicylate intoxication. For diffuse or pustular rashes, erythromycin can be helpful.

Prickly heat can be prevented by wearing light, loose-fitting, clean clothing and the avoidance of situations that produce continuous sweating. Routine use of talcum or baby powder should be avoided.

HEAT EXHAUSTION

Physiology

Heat exhaustion (heat prostration) is a clinical syndrome characterized by volume depletion that occurs under conditions of heat stress. Two types of heat exhaustion are classically described: water depletion and salt depletion. Water depletion heat exhaustion results from inadequate fluid replacement by individuals working in a hot environment, usually laborers, athletes, military personnel, or incapacitated individuals without free access to water. Those working in the heat seldom drink as much as they lose and replace only approximately two thirds of net water loss. This “voluntary dehydration” results in progressive hypovolemia. Left untreated, water depletion heat exhaustion will progress to heatstroke.

Salt depletion heat exhaustion takes longer to develop than the water depletion form. It occurs when large volumes of thermal sweat are replaced by water with too little salt. It differs from heat cramps in that systemic symptoms occur.

This syndrome is characterized by hyponatremia, hypochloremia, and low urinary sodium and chloride concentrations. Symptoms are similar to those seen in water depletion heat exhaustion; body temperature usually remains near normal.

Clinical Features

The symptoms and signs associated with both types of heat exhaustion are variable and nonspecific and include weakness, fatigue, frontal headache, impaired judgment, vertigo, nausea and vomiting, and occasionally muscle cramps (Box 139-3). Orthostatic dizziness and syncope can occur. Sweating persists and may be profuse. The core temperature is only moderately elevated, usually less than 40°C, and signs of severe CNS dysfunction are not present.

Mild heat exhaustion and full-blown heatstroke represent extremes of the spectrum of heat illness, and intermediate cases may prove difficult to differentiate. Nevertheless, heat exhaustion should not be diagnosed in the presence of major CNS dysfunction (seizures and coma) or severe hyperthermia (>40.5°C). If uncertainty exists, measurement of hepatic transaminases may prove helpful. Elevations to several thousand units can be seen in patients with heat exhaustion or in healthy runners after a marathon, whereas in patients with heatstroke, such levels are usually in the tens of thousands after 24 hours.

Management

Pure forms of either type of heat exhaustion are rare, and most cases of heat exhaustion involve mixed salt and water depletion. Heat exhaustion is primarily a volume depletion problem, and rapid recovery generally follows fluid administration. Decisions regarding the type of fluid and electrolyte replacements should be based on serum electrolyte measurements and the estimation of hydration status by clinical and laboratory parameters.

Patients with significant volume depletion or electrolyte abnormalities generally require intravenous fluids. If the patient is orthostatic, normal saline should be administered until he or she is hemodynamically stable. Free water deficits should be replaced slowly over 48 hours so as not to decrease serum osmolality more than 2 mOsm/hr. Overly rapid correction of hyponatremia is associated with seizures caused by cerebral edema.

Disposition

Young, otherwise healthy patients who do not have significant laboratory abnormalities and who respond rapidly to hydration do not require hospitalization. These patients can be discharged with instructions to drink plenty of fluids and avoid heat stress for 24 to 48 hours. Older patients, particularly those...

with cardiovascular disease or other predisposing factors described in figure 139-3, require more cautious fluid and electrolyte replacement and frequent reassessment. They are best managed as inpatients (box 139-4).

HEATSTROKE

In the previously discussed forms of heat illness, although the body temperature rises, homeostatic thermoregulatory mechanisms remain intact. Heatstroke is the catastrophic life-threatening emergency that occurs when these mechanisms fail. This failure results in elevation of body temperature to extreme levels, usually greater than 40.5°C (105°F), producing multisystem tissue damage and organ dysfunction.

Physiology

As heatstroke develops, energy will be insufficient to sustain thermoregulatory mechanisms, resulting in dramatic increases in core temperature and the clinical manifestations of heatstroke. An exact temperature at which cellular damage begins to occur in an individual patient varies. Credible reports exist of full recovery despite rectal temperatures of 44.4°C to 46.5°C. Damage is a function not only of temperature but also of the exposure time. The resultant damage to tissues is a function of a complex interaction of body temperature, exposure time, work load, tissue perfusion, and individual factors, which vary markedly.

Neurologic dysfunction is a hallmark of heatstroke, and cerebral edema is common. Other pathologic changes include petechiae in the walls of the third and fourth ventricles and marked cerebellar Purkinje cell damage. Interestingly, the hypothalamus, the predominant site of central thermoregulatory control, is usually not damaged.

Heat stress creates tremendous demands on the cardiovascular system, and patients who succumb to heatstroke show signs of circulatory failure. Although such pathologic changes are common, cardiac damage alone is not lethal.

Prolonged heat stress produces impressive increases in skin blood flow (peripheral vasodilation) and a reduction of the thermal gradient between the core and the skin. Functional hypovolemia is avoided by compensatory vasoconstriction of the splanchnic and renal vasculature. The resulting splanchic and renal ischemia may explain the nausea, vomiting, and diarrhea observed in post-marathon runners. Hepatic damage is such a consistent feature of heatstroke that its absence should cast doubt on the diagnosis. This is manifested pathologically by centrilobular necrosis with extensive cholestasis.

If severe heat stress continues, compensatory splanchic vasoconstriction will eventually fail. Failure to perfuse the skin with heated blood from the core results in a dramatically increased rate of heat storage. This produces elevated intracranial pressure, which, in combination with a reduction in mean arterial pressure caused by failure of compensatory splanchic vasoconstriction, conspires to produce a decrease in cerebral blood flow. This results in the major CNS dysfunction characteristic of heatstroke.

Clinical Features

Heatstroke versus Heat Exhaustion

The onset of heatstroke is sudden, and the patient’s level of consciousness is altered. Prodromal symptoms lasting minutes to hours occur in approximately 20% of cases. These are nonspecific and may include weakness, dizziness, nausea, vomiting, anorexia, frontal headache, confusion, drowsiness, disorientation, muscle twitching, ataxia and signs of cerebellar dysfunction, and psychiatric symptoms ranging from anxiety and irritability to psychosis.

These prodromal symptoms are reminiscent of the description of heat exhaustion. Heat exhaustion, particularly the water depletion variety, can progress to heatstroke if untreated. These two syndromes should be considered extremes on a spectrum of responses to heat stress. Heatstroke occurs when the thermoregulatory responses are overwhelmed and fail. If the patient is evaluated as this is occurring, differentiation between heat exhaustion and heatstroke is very difficult. If heatstroke cannot be excluded, efforts to cool the patient should begin immediately.

The usual manifestations of heatstroke include hyperpyrexia above 40.5°C, profound CNS dysfunction, and hot skin (box 139-5). Persistent sweating can be observed in patients with rectal temperatures of 41.5°C to 42.4°C with heatstroke. In one large series of exertional heatstroke victims, sweating persisted in 50% of cases. Therefore, the cessation of sweating is not the cause of heatstroke, and continued sweating does not preclude the diagnosis.

Although in heatstroke the core temperature is elevated above 40.5°C, significant cooling may occur in the out-of-hospital phase, and the first temperature obtained in the emergency department may not represent the original maximum core temperature.
**BOX 139-5** **HEATSTROKE: DIAGNOSIS**

Exposure to heat stress, endogenous or exogenous

Signs of severe CNS dysfunction (coma, seizures, delirium)

Core temperature usually above 40.5° C (105° F), but may be lower

Hot skin common, and sweating may persist

Marked elevation of hepatic transaminases

**Classic Heatstroke versus Exertional Heatstroke**

The two forms of heatstroke have significantly different presentations and manifestations: classic (epidemic) heatstroke (CHS) and exertional heatstroke (EHS) (Table 139-1).

**Classic heatstroke** occurs during periods of sustained high ambient temperatures and humidity, such as during summer heat waves. Victims are often elderly and poor and live in underventilated dwellings without air-conditioning. Debilitated patients who have limited access to oral fluids may develop heatstroke if untreated. Victims of CHS commonly suffer from chronic diseases, alcoholism, or schizophrenia, which predispose to heat illness. Such patients are often prescribed medications (e.g., diuretics, antihypertensives, neuroleptics, and anticholinergics) that impair the ability to tolerate heat stress. Sweating ceases in the majority of CHS patients. Factors such as advanced age, hypotension, altered coagulation status, and the necessity for endotracheal intubation on arrival at the emergency department predict a poor outcome despite successful cooling measures.

In contrast, patients with EHS are usually young and healthy individuals whose heat-dispersing mechanisms are overwhelmed by endogenous heat production. Athletes and military recruits are typical victims. Rhadomyolysis and acute renal failure, rarely seen in patients with CHS, are common in patients with EHS. Sweating is present in half the cases of EHS. Hypoglycemia may occur as the result of increased glucose metabolism and hepatic damage resulting in impaired gluconeogenesis. Coagulopathy is common. Hypokalemia with serum sodium levels less than 130 mmol/L has been detected in summer hikers in the Grand Canyon; many present with neurologic symptoms or seizures.

Signs of profound CNS dysfunction dominate the early course of heatstroke. Delirium or coma is characteristic, but virtually any neurologic abnormality, including bizarre behavior, opisthotonus, hallucinations, decerebrate rigidity, oculogyric crisis, and cerebellar dysfunction, can be seen. Convulsions occur in up to 75% of patients and can be precipitated by therapeutic cooling maneuvers. Profound muscle rigidity with tonic contractions, coarse tremor, and dystonic movements can mimic seizures. Pupils may be fixed and dilated, and the electroencephalogram may be isoelectric. All these changes are potentially reversible, although permanent damage, including cerebellar deficits, hemiplegia, dementia, and personality changes, is common in severe cases. Patients with heatstroke usually have hyperdynamic cardiovascular systems with low peripheral vascular resistance, tachycardia (up to 180 beats/min), and an elevated cardiac index. The central venous pressure (CVP) is usually elevated. The combination of elevated CVP with right-sided cardiac dilation suggests right-sided cardiac failure, which is also seen after shock or sepsis. These changes are expected because skin blood vessels dilate to dissipate heat; however, this low peripheral vascular resistance has persisted in patients after reduction of body temperature to near normal.

Respiratory alkalosis is a physiologic response to active or passive heating and may be severe enough to produce tetany. Although most patients with CHS have respiratory alkalosis, those with EHS usually have a relatively pure lactic acidosis. Lactic acidosis is associated with a poor prognosis in cases of CHS but not necessarily in cases of EHS.

Aberrations in coagulation are common in patients with severe heatstroke, and their presence is a poor prognostic sign (Fig. 139-4). Abnormal hemostasis is manifested clinically by purpura, conjunctival hemorrhage, melena, bloody diarrhea, hemoptysis, hematuria, myocardial bleeding, or hemorrhage into the CNS.

Hepatic damage is so consistently featured in heatstroke that its absence should cast doubt on the diagnosis. Hepatic injury is evidenced by markedly elevated levels of hepatic aminotransferases (serum aspartate transaminase and alanine transaminase). Jaundice typically appears 24 to 72 hours after the onset of severe heatstroke and gradually recedes if the victim survives. Survivors generally have no permanent impairment of liver function. Hypoglycemia with a serum glucose level less than 65 mg/dL is common in cases of exertional heatstroke.

Renal damage is common. The initial urine specimen, usually obtained by catheterization, is a scanty, brownish, turbid fluid resembling machine oil. Microscopic examination
reveals proteinuria with abundant granular casts and red blood cells. Acute oliguric renal failure complicates 25 to 30% of EHS cases and 5% of CHS cases. Glomerular filtration rate, renal plasma flow, urine flow, and sodium excretion diminish markedly during exercise. Heavy physical exertion in hot climates produces acidic and maximally concentrated urine, which can result in acute oliguric renal failure when combined with hypotension and myoglobinuria.49 Cocaine use is also associated with rhabdomyolysis and hyperthermia.48

Diarhea, probably caused by intense splanchnic vasoconstriction, is commonly seen. Cooling aggravates the diarrhea, creating an unpleasant treatment problem. Pancreatitis is described with elevated serum amylase and lipase levels.

Diagnostic Strategies

Thermometry

Unfortunately, most standard measurements of body temperature vary significantly from the actual core temperature. Oral thermometry is affected by mouth breathing and is a poor approximation of the core. Rectal thermometry is less variable but responds to changes in core temperature slowly. Thermistors that are inserted 15 cm into the rectum offer continuous monitoring of temperature and less variability. Although slower to respond to changes in core temperature than tympanic temperature readings, rectal measurements are not biased by head skin temperature. An esophageal thermistor positioned adjacent to the heart is another option.

Placement of a tympanic temperature sensor directly on the tympanic membrane is difficult and is not used clinically. Commercially available infrared thermometers do not physically contact the tympanic membrane and are unreliable in detecting hyperthermia.49 If a patient is being monitored with a catheter, pulmonary arterial temperature can be measured precisely with a thermistor catheter.

Only after the initial assessment and cooling have begun is the differential diagnosis relevant. When a history of collapse under conditions of heat stress is present, rapid improvement in mental status and blood pressure with cooling eliminates alternative diagnoses. If, however, the temperature does not respond and the patient does not recover neurologically, other causes of fever and coma must be considered (Box 139-6).

The history may be helpful; shaking chills suggest fever with an altered hypothalamic set point rather than heat illness. Meningitis and encephalitis can masquerade as heatstroke. In patients with heatstroke, the spinal fluid should be crystal clear, with occasional lymphocytic pleocytosis and elevated protein levels. Cerebral falciparum malaria, which presents a clinical picture of high fever and encephalitis, is seen in tropical areas where heat illness can also occur.

In patients with thyroid storm, the clinical symptoms resemble those of heatstroke. It should be suspected if the thyroid gland is enlarged or nodular, but a normal thyroid gland does not exclude the diagnosis. Thyroid function test results are elevated, but these are not available on an emergency basis. Fortunately, thyroid storm is rare, and some critical aspects of treatment, such as rapid cooling, coincide with those for heatstroke.

Drug-induced heat illness is an important consideration, particularly anticholinergic poisoning. Differentiation may be difficult because both heatstroke and anticholinergic poisoning produce hyperpyrexia, hot and dry skin, tachycardia, and abnormal mental status. Constricted pupils are present in many heatstroke patients.50 Mydriasis should be present in patients with anticholinergic poisoning, and its absence argues strongly against this diagnosis. Typhoid fever, typhus, delirium tremens, and hypothyroidal hemorrhage all produce symptom complexes similar to that of heatstroke.

Malignant hyperthermia and neuroleptic malignant syndrome are characterized by “lead pipe” rigidity. The serotonin syndrome can also mimic heatstroke because of the elevated body temperature temors and CNS alterations that occur. Serotonin syndrome is classically a triad of mental status changes, autonomic hyperactivity, and neuromuscular abnormalities secondary to increased CNS serotonergic activity. Recent exposure to illicit or therapeutic medication is important.

Hepatic transaminase elevations may be diagnostically helpful. In most febrile states that include altered mental status or coma, these enzymes will be normal or minimally elevated, although they are usually dramatically elevated early in the course of heatstroke.

MANAGEMENT

It does not take long either to boil an egg or to cook neurons. 

D. Hamilton51

Cooling

Immediate cooling is the cornerstone of treatment. Mortality correlates with the temperature and the number of dysfunctional organ systems, with an increased risk of death if patients present with anuria, coma, or cardiovascular failure.4 Patients who present to the hospital with heat stroke have high mortality rates ranging from 21 to 63%,52 and mortality increases significantly when cooling is delayed.53,54 Cooling efforts take precedence over any time-consuming search for the cause. In the out-of-hospital setting, cooling should be initiated after removing the patient from the hot environment. When the patient arrives at the hospital, clothes should be removed, a thermistor probe should be inserted, and the temperature should be continuously monitored.

The ideal method of evaporative cooling uses a body cooling unit on which the patient lies suspended on a net surface while being sprayed with atomized 15° C water from above and below.55 Air warmed to 45° C to 48° C is blown over the skin surface at 3 m/min. The unit, not widely available, maximizes evaporative cooling by maintaining cutaneous vasodilatation and avoiding heat generation caused by shivering.

Less complex equipment can also be used to maximize evaporative cooling. Evaporative cooling is the most widely used cooling method. The combination of atomized tepid water at 40° C from a spray bottle and standing fans cool at rates comparable to both body cooling unit and immersion.56

CNS, central nervous system.
Other evaporative techniques, including the use of downright from a helicopter, can be applied successfully.57

Immersion in ice water results in a rapid reduction of core temperature to less than 39°C within 10 to 40 minutes but complicates the resuscitation.58 Vigorous skin massage to maintain cutaneous circulation has been advocated, but there is no objective evidence that this is efficacious. When the body temperature reaches 39°C, cooling measures should be discontinued to avoid hypothermic overshoot. Continuous monitoring is necessary to maintain the core temperature at 37°C to 38°C.54

Military studies of EHS patients treated with ice water immersion have reported no fatalities or permanent sequelae.51 A mortality rate of 14% was reported in a study of 28 patients with CHS treated by immersion.50 Immersion is technically difficult in the emergency department. Vasoconstriction from ice water immersion may be beneficial to hypotensive patients and may be better than evaporative cooling for victims in shock who have poor peripheral circulation.

Cooling modalities other than evaporation and immersion should be considered adjunctive treatments (Box 139-7). Application of ice packs to high heat transfer areas (neck, groin, and axillae) is commonly used. Cooling blankets may be a useful adjunct but will not produce rapid cooling if used exclusively. Cardiopulmonary bypass with a heat exchanger has been successful in the treatment of malignant hyperthermia.58 Peritoneal dialysis with cold fluids, although successful in a canine model, remains untested in humans. Cold-irrigant gastric or rectal lavage will not provide significant heat exchange if used as the primary cooling modality.

**Resuscitation**

Aspiration and seizures are common in patients with heatstroke, and airway control is essential.59 Hypoxemia may occur because of aspiration, pneumonitis and pulmonary infarction, hemorrhage, or edema. Metabolic demands are high, and normal pulmonary ventilation may be inadequate in this setting.

Circulatory fluid requirements are modest in some cases, averaging 1200 mL of isotonic crystalloid solution in the first 4 hours. Pulmonary edema occurs in patients with heatstroke and can be exacerbated by overzealous fluid administration. The use of a CVP catheter to monitor fluid resuscitation may be deceptive. Most patients have a hyperdynamic circulation with high cardiac index, low peripheral vascular resistance, and elevated CVP as a result of right-sided heart failure. These patients may require only modest intravenous fluids because cooling produces vasoconstriction and increases blood pressure.60 Nevertheless, crystalloid resuscitation is essential.

Hypotension is common in patients with heatstroke and is usually caused by peripheral vasodilation resulting in high-output cardiac failure, in addition to dehydration. Blood pressure usually rises with cooling. If this does not occur, or if the patient monitored invasively has a low central venous pressure, a fluid challenge of 250 to 500 mL of 0.9% saline should be given rapidly while blood pressure, pulse, and urine output are monitored. If the blood pressure rises, further fluids are given with careful monitoring of the CVP. Aggressive fluid replacement is continued until the blood pressure reaches 90/60 mm Hg or the CVP exceeds 12 mL H2O. Occasionally, patients exhibit hypodynamic responses with low cardiac index, elevated CVP, and hypotension. These patients may be cyanotic, whereas patients with hyperdynamic circulation are initially pink. This clinical observation can be helpful in identifying patients who may respond to catecholamines.

A variety of tachyarrhythmias commonly occur during heatstroke. These usually resolve with cooling, and electrical cardioversion should be avoided until the myocardium is cooled. The use of alpha-adrenergic agents such as norepinephrine is not recommended because they promote vasoconstriction without improving cardiac output or perfusion, decrease cutaneous heat exchange, and may enhance ischemic renal and hepatic damage. Atropine and other anticholinergic drugs that inhibit sweating should be avoided.

Because the pathophysiology of heatstroke and fever differ, antipyretics are not indicated and may be harmful. Salicylates, particularly in large doses, can worsen hyperthermia by uncoupling oxidative phosphorylation and aggravate coagulopathies. Large doses of acetaminophen can result in further hepatic damage. The efficacy of dantrolene is not established.61

If rhabdomyolysis is present, maintenance of urinary output of at least 2 mL/kg/hr is required.62 Urinary alkalinization has been supported by animal studies and retrospective reviews, and it should be considered early in patients with acidemia, dehydration, or underlying renal disease. Urine pH should be titrated to greater than 6.5. After volume repletion, administration of mannitol may be considered to increase intravascular volume and increase glomerular filtration rate. Mannitol should not be used in an oliguric patient.63 Persistent anuria, uremia, or hyperkalemia is an indication for consideration of hemodialysis.

Hematologic evaluation should include arterial blood gas determination; complete blood cell count and platelet counts; electrolytes, blood urea nitrogen, glucose, creatinine, aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, creatine phosphokinase, uric and lactic acid, and calcium levels; prothrombin and partial thromboplastin times; international normalized ratio; and fibrin degradation products and hepatic enzymes. Bedside cardiac markers should be considered. Acidosis is common, especially in patients with exocrino heatstroke. Lactate levels are usually elevated; this may persist or even worsen with improved extremity perfusion.

Cooling modalities that drastically lower skin temperature may induce violent shivering; this increases metabolic heat production and may impede cooling. In this situation, intravenous benzodiazepines or chlorpromazine (25–50 mg intravenously) can be efficacious. Chlorpromazine has anticholinergic properties that can interfere with sweating and cause hypotension or, rarely, precipitate seizures. Therefore, its use should be reserved for instances when cooling is not adequate because of vigorous shivering.

Many patients are extremely agitated during the initial cooling period. Short-acting benzodiazepines can be used for sedation and to control seizures.64 Barbiturates are less desir-
able for treatment of seizures since metabolism is altered by hepatic dysfunction.

Coagulopathies can occur during the first day of illness but are more common on the second and third days. Initial treatment after cooling should include replacement therapy with fresh frozen plasma and platelets.\textsuperscript{46} The clinician should monitor the laboratory signs of disseminated intravascular coagulation (hypofibrinogenemia, elevated fibrin split products, prolonged prothrombin time, and thrombocytopenia).\textsuperscript{46} The bleeding diathesis in patients with heatstroke may be the result of fibrinolysis. Although $\alpha$-amino caproic acid can impede fibrinolysis, administration of this compound is associated with rhabdomyolysis and its use is not recommended in patients with heatstroke.

CHAPTER 140  Electrical and Lightning Injuries

Timothy G. Price and Mary Ann Cooper

**PERSPECTIVE**

**Electrical Injury**

The first recorded death caused by electrical current from an artificial source was reported in 1879 when a carpenter in Lyons, France, inadvertently contacted a 250-V alternating current (AC) generator. The first U.S. fatality occurred in 1881 when an inebriated man passed out on a similar generator in front of a crowd in Buffalo, New York. In the United States, electrical burns account for 4 to 6.5% of all admissions to burn units and approximately 1000 fatalities per year. Occupational electrical incidents are uncommon but account for nearly 6% of all occupational fatalities annually. Children have a predisposition to injuries from low-voltage sources, such as electric cords, because of their limited mobility within a relatively confined environment. During adolescence, a more active exploration of the environment leads to more severe high-voltage injuries or death. At the time of presentation, documentation of injuries is important not only for the immediate resuscitation of the victim but also for medicolegal reasons. Many electrical injuries eventually involve litigation for negligence, product liability, or worker compensation.

**Lightning Injury**

The incidence of injury and death from lightning is unknown since no agency requires the reporting of lightning injuries, and some victims do not seek treatment at the time of their injury. The incidence of lightning-related deaths in the United States has declined to an average of 62 people annually. Lightning is fatal in 1 of 10 lightning strike victims. In typical years, lightning kills more people in the United States than any other natural disaster except floods, and it is consistently among the top four weather-related killers (Fig. 140-1). Participants in sports and recreational activities are common victims; mountain activities, golf, ball field games, and water activities account for the largest numbers of fatalities and injuries. Outdoor workers, particularly on construction sites or on farms, are also vulnerable. Lightning incidents often involve more than one victim when the current “splashes” to other individuals or as ground current spreads the electrical power throughout the area where a group is sheltered in a storm. The largest number of victims reported from a single lightning strike is 35 (28 people and 7 dogs). All of the victims were sleeping in a large tent, and 4 children and 4 dogs were fatally injured.

Certain snowy conditions can also result in lightning and put skiers at risk for lightning injury. The formation of sleet and graupel, a type of frozen precipitation sometimes referred to as snow pellets or soft hail, reflects large differences in electrical potential in the atmosphere. Winter sports enthusiasts should recognize graupel and appreciate the associated lightning risks.

**PRINCIPLES OF DISEASE**

**Physics of Injury**

The exact pathophysiology of electrical injury is not well understood because of the numerous variables that cannot be measured or controlled when an electrical current passes through tissue. With high voltage, most of the injury seems to be thermal, and histologic studies reveal coagulation necrosis consistent with thermal injury. The theory of electroporation is that electrical charges insufficient to produce thermal damage cause protein configuration changes that threaten cell wall integrity and cellular function.

The nature and severity of electrical burn injury are directly proportional to the current strength, resistance, and duration of current flow (Box 140-1). Current strength is expressed in amperes and is a measure of the amount of energy flowing through an object. Current is determined by the voltage and resistance. Resistance is determined by the current’s pathway through the body. The factors determining the severity of burn injury are summarized in Box 140-2.

**Type of Circuit**

One of the factors affecting the nature and severity of electrical injury is the type of circuit involved, either direct current (DC) or AC. High-voltage DC contact tends to cause a single muscle spasm, often throwing the victim from the source. This results in a shorter duration of exposure but increases the likelihood of traumatic blunt injury. Brief contact with a DC source can also result in disturbances in cardiac rhythm, depending on the phase of the cardiac cycle affected.

AC exposure of the same voltage tends to be three times more dangerous than DC. Continuous muscle contraction, or tetany, can occur when the muscle fibers are stimulated between 40 and 110 times per second. The standard frequency of electrical transmission in the United States is 60 Hz (cycles per second), which is near the lowest frequency at which an incandescent light appears to be continuously lit.
The terms *entry* and *exit* are commonly used to describe electrical injury patterns. The terms *source contact point* and *ground contact point* are more appropriate, however, when referring to AC injuries. The hand is the most common site of contact via a tool that is in contact with an AC electrical source. Because the flexors of the hand and forearm are much stronger than the extensors, contraction of the flexors at the wrist, elbow, and shoulder occurs, causing the hand grasping the current source to pull the source even closer to the body. Currents greater than the “let-go threshold” (6–9 mA) can prevent the victim from releasing the current source, which prolongs the duration of exposure to the electrical current.

**Resistance**

*Resistance* is the tendency of a material to resist the flow of electrical current. It is specific for a given tissue, depending on its moisture content, temperature, and other physical properties. The higher the resistance of a tissue to the flow of current, the greater the potential for transformation of electrical energy to thermal energy. Nerves, designed to carry electrical signals, and muscle and blood vessels, because of their high electrolyte and water content, have a low resistance and are good conductors. Bone, tendon, and fat, which all contain a large amount of inert matrix, have a high resistance and tend to heat and coagulate rather than transmit current. The other tissues of the body are intermediate in resistance (Box 140-3).

Skin is the primary resistor to the flow of current into the body. Skin on the inside of the arm or back of the hand has a resistance of approximately 30,000 Ω/cm². Hardened skin can have 20 to 70 times greater resistance (Table 140-1). This high resistance may result in a significant amount of energy being expended at the skin surface as the current burns its way through deep callus, resulting in greater thermal injury to the skin but less internal damage than would be expected if the current is delivered undiminished to the deep tissues. As the duration of contact increases, however, the skin begins to blister and offer decreased resistance. A surge of current internally can cause extensive deep tissue destruction. Moisture also lowers resistance. Sweating can decrease the skin’s resistance to 2500 to 3000 Ω/cm², and immersion in water causes a further reduction to 1200 to 1500 Ω/cm².

**Amperage**

*Current*, expressed in amperes, is a measure of the amount of energy that flows through an object. As defined by Joule’s law, the heat generated is proportional to the amperage squared.
Amperage depends on the source voltage and the resistance of the conductor and normally must be estimated in human electric exposures. Although the voltage of the source is often known, the resistance varies according to the involved tissues. In addition, as tissue changes occur secondary to the energy of the current flow, resistance may change markedly, rendering predictions of amperage difficult for any given electrical injury.

The physical effects vary with different amperages at 50 to 60 Hz, which is the AC frequency used in European countries and the United States (Table 140-2). A narrow range exists between the threshold of perception of current (0.2–0.4 mA) and let-go current (6–9 mA). The let-go current is the level above which muscular tetany prevents release of the current source. Thoracic tetany also can occur at levels just above this let-go current and result in respiratory arrest. Ventricular fibrillation occurs at an amperage of 60 to 120 mA. Dry skin in contact with a 120-V household source results in significantly lower current than the same voltage across skin submerged in water. This wet skin may result in current sufficient to cause electrocution with cardiac arrest with no surface burns.

### Duration of Contact

The longer the duration of contact with high-voltage current, the greater the electrothermal heating and degree of tissue destruction. When carbonization of tissue occurs, the resistance to current flow increases. The physics differ with lightning. The extremely short duration and extraordinarily high voltage and amperage of lightning result in a short flow of current internally, with little, if any, skin damage and almost immediate flashover of current around the body.

### Voltage

Voltage is a measure of the difference in electrical potential between two points and is determined by the electrical source. Electrical injuries are conventionally divided into low or high voltage, with 1000 V the most commonly used divider. Although both can cause significant morbidity and mortality, high voltage results in greater current flow and has a greater potential for tissue destruction and amputations.

No fatalities are recorded from contact with the low voltages associated with long-distance communication lines (24 V) or telephone lines (65 V). Fatalities are reported, however, with exposure to 110-V household current, especially in special environmental circumstances such as bathtub-related electrocutions.

### Pathway

The pathway of low, high, or lightning voltages determines the tissues at risk, the type of injury, and the degree of conversion of electrical energy to heat. Current passing through the heart or thorax can cause dysrhythmias and direct myocardial damage. Cerebral current can result in respiratory arrest, seizures, and paralysis. Current with ocular proximity can cause cataracts.

Truncal current causes less damage than current that passes through a single digit. As current density increases, its tendency to flow through the less resistant tissues is overcome. Eventually it flows through tissues indiscriminately, as if the body were a volume conductor, with the potential to destroy all tissues in the current’s path. Because the current is often concentrated at the source and ground contact points, the greatest degree of damage is often observed there. Nevertheless, extensive deep destruction of the tissues may exist between these sites with high-voltage injuries, and the surface damage is often only “the tip of the iceberg.” Damage to the internal structures of the body may be noncontiguous, with areas of normal-appearing tissue adjacent to burned tissue and with damage to structures at sites distant from the apparent contact points.

The pathway between contact points is a major determinant of the electrical field strength, which is the voltage per unit of length. For a given current, the shorter the distance between contact points, the greater the electrical field strength. Current from a 20,000-V power line passing from head to toe (approximately 2 m) results in an electrical field strength of 10,000 V/m. Approximately the same electrical field strength is created when 120-V household current passes between two close contact points on the mouth of a child chewing on a power cord (120 V/0.01 m). Although the electrical field strengths are similar, there is a tremendous difference in the amount of at-risk tissue in the respective pathways.

Although lightning is governed by the same physical laws as artificial electricity, the rapid rise and decay of the energy complicates predictions of the extent of lightning injury more than artificial electrical injury. The most important difference between lightning and high-voltage electrical injuries is the duration of exposure to the current.

Lightning is neither a direct current nor an alternating current but, rather, a unidirectional massive current impulse. Lightning is classed as a current, rather than a voltage, phenomenon. The cloud-to-ground lightning impulse results from the breakdown of a large electrical field between a cloud and the ground that is measured in millions of volts. When connection is made with the ground, this voltage difference between the cloud and ground disappears, and a large current flows impulsively for a short time.

### Resistance

- Mucous membranes: 100 Ω/CM²
- Vascular areas: 300–10,000 Ω/CM²
- Volar arm, inner thigh: 1,200–1,500 Ω/CM²
- Wet skin: 2,500 Ω/CM²
- Bathrub: 10,000–40,000 Ω/CM²
- Sole of foot: 100,000–200,000 Ω/CM²
- Heavily calloused palm: 1–2 million Ω/CM²
Mathematical modeling of a lightning strike to the human body is substantiated on animal models. After lightning meets the body, current initially is transmitted internally, after which skin breaks down, and ultimately external “flashover” occurs. A fast flashover appreciably diminishes the energy dissipation within the body and can result in survival.

Although lightning current may flow internally for an instant and short-circuit electrical systems, it seldom causes significant burns or tissue destruction. Burns and myoglobinuric renal failure are not a common injury pattern from lightning. More common manifestations include cardiac and respiratory arrest, vascular spasm, neurologic damage, and autonomic instability.

Lightning tends to cause asystole rather than ventricular fibrillation. Although cardiac automaticity may reestablish a rhythm, the duration of the respiratory arrest may cause secondary deterioration of the rhythm to refractory ventricular fibrillation and asystole. This secondary arrest occurs experimentally in sheep. Other injuries caused by blunt trauma or ischemia from vascular spasms, such as myocardial infarction or spinal artery syndromes, also occur.

Mechanisms of Injury

Electrical Injury

The primary electrical injury is the burn. Secondary blunt trauma results from falls or being thrown from the electrical source by an intense muscular contraction or the explosive force that may occur with electric flashes from circuit box or transformer accidents. Electrical burns are classified into four different types (Box 140-4).

Heating of tissues secondary to current causes electrothermal burns. Usually, these burns are a result of a low-voltage shock with a limited affected area. Severe electrothermal burns can occur, however, if a person grips a high-voltage conductor. The prolonged flow of current can result in significant burns anywhere along the current path. Typically, the skin lesions of electrothermal burns are well-demarcated, deep, partial-thickness to full-thickness burns.

The most destructive indirect injury occurs when a victim becomes part of an electrical arc. An electrical arc is a current spark formed between two objects of differing potential that are not in contact with each other, usually a highly charged source and a ground. Because the temperature of an electrical arc is approximately 2500°C, it causes deep thermal burns at the point where it contacts the skin. With electrical arcs, burns may be caused by the heat of the arc, electrothermal heating due to current flow, or flames that result from the ignition of clothing. Instead of a discrete arc, current may jump the gap by splashing across the entire body. These splash burns may cover a large portion of the body but are generally only partial thickness.

At the time of presentation, it is often difficult to determine the mechanism of injury that caused an electrically injured patient’s burns. Electrothermal heating is the main cause of muscle damage and is seen almost exclusively in high-voltage accidents with prolonged (seconds) contact and current flow.

The histologic change in muscle injury that results from direct contact with an electrical source is coagulation necrosis with shortening of the sarcomere. Muscle damage can be erratic, so areas of viable and nonviable muscle are often found in the same muscle group. Periosteal muscle damage may occur even though overlying muscle appears to be normal. Similar to the muscle damage, serious vascular damage usually occurs only after a high-voltage accident.

Vascular damage is greatest in the media; this can lead to delayed hemorrhage when the vessel eventually ruptures.

Intimal damage may result in either immediate or delayed thrombosis and vascular occlusion as edema and clots form on the damaged intimal surface of the vessel over a period of days. The injury is usually most severe in the small muscle branches, where blood flow is slower. This damage to small muscle arteries, combined with mixed muscle viability that is not visible to gross inspection, creates the illusion of “progressive” tissue necrosis.

The absence of a pulse on initial examination may be a result of immediate arterial thrombosis or transient vascular spasm. Pulselessness resulting from vascular spasm should resolve within a few hours. If pulselessness persists after this time, serious vascular injury is likely.

Damage to neural tissue also may occur via several mechanisms. An immediate decrease in neural conductivity occurs with coagulation necrosis similar to that observed in muscle. In addition, it may suffer indirect damage as its vascular supply or myelin sheath is injured or as progressive edema results in a compartment syndrome. Evidence of neural damage may develop immediately or be delayed hours to days. The skull is a common contact point. Histologic studies of the brain reveal focal petechial hemorrhages in the brainstem, cerebral edema, and widespread chromatolysis (the disintegration of chromophil bodies of neurons).

Lightning Injury

Lightning injury may occur by electrical mechanisms (Box 140-5) and by secondary blunt trauma. Lightning strikes near the head may enter orifices such as the eyes, ears, and mouth to flow internally, which may help explain the myriad reported eye and ear symptoms and signs.

Injury from contact occurs when the person is touching an object that is part of the pathway of lightning current, such as a tree or tent pole. Side flash or splash occurs as lightning jumps from its primary strike object to a nearby person on its way to the ground. Step voltage, a difference in electrical potential between a person’s feet, may occur as lightning current spreads radially through the ground. A person is a far better conductor of electricity than the earth. A person who has one foot closer than the other to the strike point has a potential difference between the feet so that the lightning current preferentially flows through the legs and body rather than through the torso.

than the ground. This ground current is a common killer of large livestock such as cattle and horses because of the distance between their hind legs and forelegs.

Victims of lightning injury may also be exposed to low-current upward streamers or ball lightning. Cloud-to-ground lightning approaches the earth as charged downward leaders. As the leaders approach, the large electrical field induces a buildup of ground charges that surge upward as upward streamers. This upward surge can travel through objects, including people. If the upward streamer connects with a downward leader, a completed lightning strike occurs. Not all upward streamers connect. Individuals in the path of an upward streamer may be injured even in the absence of a completed lightning strike. Ball lightning is a mobile, luminous, spherical, floating or bouncing ball of plasma that lasts a few seconds before suddenly vanishing or exploding.26 These glowing orbs have been observed traveling down power lines and the aisles of aircraft.

Blunt injury from lightning can occur from two mechanisms. First, the person may be thrown a considerable distance by the sudden, massive contraction caused by current passing through the body. Second, an explosive or implosive force occurs as the lightning pathway is instantaneously superheated then rapidly cooled after the passage of the lightning. The heating is seldom long enough to cause severe burns, but it does cause rapid expansion of air followed by rapid implosion of the cooled air as it rushes back into the void.

### CLINICAL FEATURES

Patients with high-voltage injury commonly present with devastating burns. Patients with lightning injury and low-voltage injury may have little evidence of injury or, alternatively, may be in cardiopulmonary arrest. After the initial resuscitation of lightning and low-voltage injuries, other conditions may be identified. These patients may have significant residual morbidity from pain syndromes or cerebral damage.

### Head and Neck

#### Electrical Injury

The head is a common point of contact for high-voltage injuries, and the patient may exhibit burns and neurologic damage. Cataracts develop in approximately 6% of patients with high-voltage injuries, especially whenever electrical injury occurs in the vicinity of the head. Although cataracts may be present initially or develop soon after the accident, they more typically appear months after the injury. Visual acuity and funduscopic examination should be performed at presentation. Hearing loss is much less common.27

#### Lightning Injury

Lightning strikes may cause skull fractures and cervical spine injury from associated blunt trauma.16,19 Tympanic membrane rupture is commonly found in lightning victims and may be secondary to the shock wave, a direct burn, or a basilar skull fracture.17 Although most patients recover without serious sequelae, disruption of the ossicles and mastoid, otorrhea, hematympanum, perilymphatic fistulae, and permanent deafness may occur.28,29

Ocular injuries include corneal lesions, uveitis, iridocyclitis, hyphema, vitreous hemorrhage, optic atrophy, retinal detachment, and choroidoretinitis. As a result, dilated, unreactive pupils are not a reliable indicator of death. As with electrical injuries, cataracts may develop later in some patients.17

### Cardiovascular System

#### Electrical Injury

Cardiac arrest, either from asystole or from ventricular fibrillation, is common in electrical accidents. Other electrocardiographic findings include sinus tachycardia, transient ST segment elevation, reversible Q-T segment prolongation, premature ventricular contractions, atrial fibrillation, and bundle branch block. Acute myocardial infarction is relatively rare. Damage to skeletal muscles may produce an increase in cardiac biomarkers leading to a spurious diagnosis of myocardial infarction.

#### Lightning Injury

In lightning injury, cardiac arrest may be caused by the electrical shock or induced vascular spasm.30 Numerous dysrhythmias occur in the absence of cardiac arrest.14 Nonspecific ST-T wave segment changes and prolongation of the Q-T interval may occur, and serum levels of cardiac enzymes are often elevated.31,32 Hypertension is commonly present after lightning injury but usually resolves without treatment within a few hours.

### Skin

#### Electrical Injury

Other than cardiac arrest, the most devastating injuries are burns, which are most severe at the source and ground contact points. The most common sites of contact with the source include the hands and the skull. The most common areas of ground contact are the heels. A patient may have multiple source and ground contact points. Burns in severe electrical accidents often appear as painless, depressed, yellow-gray, punctate areas with central necrosis, or the areas may be mummified.12 High-voltage current often flows internally and can create massive muscle damage. If contact is brief, however, minimal flow may have occurred, and the visible skin damage may represent nearly all of the damage. Prediction of the amount of underlying tissue damage from the amount of cutaneous involvement is not possible.

A peculiar type of burn associated with electrical injury is the “kissing burn,” which occurs at the flexor creases (Fig. 140-2).12 As the current causes flexion of the extremity, the skin of the flexor surfaces at the joints touches. Combined with the moist environment that often occurs at the flexor areas, the

---

**Figure 140-2.** Kissing burn. (Courtesy of Mary Ann Cooper, MD.)
electrical current may arc across the flexor crease, causing arc burns on both flexor surfaces and extensive underlying tissue damage.

Electrical flash burns are usually superficial partial-thickness burns, similar to other flash burns. Isolated thermal burns may also be seen when clothing ignites. The total body surface area affected by burns in electrical injury averages 10 to 25%. Severe burns to the skull and occasionally to the dura may occur.

The most common electrical injury seen in children younger than 4 years is the mouth burn that occurs from sucking on a household electrical extension cord. These burns usually represent local arc burns, may involve the orbicularis oris muscle, and are especially worrisome when the commissure is involved because of the likelihood of cosmetic deformity. A significant risk of delayed bleeding from the labial artery exists when the eschar separates. Damage to developing dentition can occur, and referral to an oral surgeon familiar with electrical injuries is recommended.18

Lightning Injury

Deep burns occur in fewer than 5% of lightning injuries.17,34 Patients may exhibit one or more of the following four types of superficial burns or skin changes: linear, punctate, feathering, or thermal burns.10,17,34 Linear burns tend to occur in areas where sweat or water accumulate, such as under the arms or down the chest. These are superficial burns that appear to be caused by steam production from the flashover phenomenon. Punctate burns appear as multiple, small cigarette-like burns, often with a heavier central concentration in a rosette-like pattern. They range from a few millimeters to 1 cm in diameter and seldom require grafting. Feathering burns are not true burns because there is no damage to the skin.34 Electron showers induced by the lightning create a fern pattern on the skin.34 These transient lesions are pathognomonic for lightning injury and require no therapy (Fig. 140-3).35 Thermal burns occur if the clothing is ignited or may be caused by metal that the person is wearing or carrying during the flashover.21

Figure 140-3. Feathering burn. (Courtesy of Mary Ann Cooper, MD.)

Extremities

Electrical Injury

In high-voltage injuries, muscle necrosis can extend to sites distant from the observed skin injury, and compartment syndromes occur as a result of vascular ischemia and muscle edema. Decompression fasciotomy or amputation is often necessary.36 Massive release of myoglobin from the damaged muscle may lead to myoglobinuric renal failure.

Joint areas may exhibit more severe injury than the muscle along the long bone portions of an extremity. Burn injury becomes concentrated at joints because there is less cross-sectional area of muscle to conduct the energy than at long bone portions. There is also a much lower proportion of muscle versus more poorly conductive tendons that cross a joint surface. In addition, as the energy is concentrated in these areas, it may cause skin surface burns, particularly where skin surfaces touch, such as the antecubital fossae.

Vascular damage from the electrical energy may become evident at any time.22 Neurovascular checks should be reassessed continually in all extremities. Because the arteries are a high-flow system, heat may be dissipated and cause little initial apparent damage but result in subsequent deterioration. In contrast, the veins are a low-flow system, allowing the heat energy to heat blood rapidly, with resulting thrombosis. Consequently, an extremity may initially appear edematous. With severe injuries, the entire extremity may appear mummified when all tissue elements, including the arteries, experience coagulation necrosis.

Damage to the vessel wall at the time of injury may also result in delayed thrombosis and hemorrhage, especially in the small arteries to muscle.22 This ongoing vascular damage can cause a partial-thickness burn to progress into a full-thickness burn as the vascular supply diminishes to the area. Progressive loss of muscle because of vascular ischemia downstream from damaged vessels may mandate repeated deep débridements.22

Lightning Injury

Lightning injury may cause transient vasospasm so severe that the extremities appear cold, blue, mottled, and pulseless. This condition usually resolves within a few hours and rarely requires vascular imaging or surgical intervention.17

Skeletal System

As with electrical injury, numerous types of fractures and dislocations are reported with lightning injury. Fractures of the long bones are possible secondary to the trauma associated with electrical injury. Posterior and anterior shoulder dislocations caused by tetanic spasm of the rotator cuff muscles and spinal fractures occur.

Nervous System

Electrical Injury

In high-voltage injuries, loss of consciousness is usually transient, unless there is a significant concomitant head injury. Prolonged coma with eventual recovery also occurs. Patients may exhibit confusion, flat affect, and difficulty with short-term memory and concentration. Electrical injury to the central nervous system may cause a seizure, either as an isolated event or as part of a new-onset seizure disorder. Other possible causes of seizures, such as hypoxia and traumatic brain injury, should be considered. Neurologic symptoms may improve, but long-term disability is common. Lower extremity weakness is commonly undiagnosed until ambulation is attempted.27

In high-voltage exposures, spinal cord injury may result from fractures or ligamentous disruption of the cervical, thoracic, or lumbar spine.37,38 Neurologic damage in patients without evidence of spinal injury can be immediate or delayed. Patients with immediate damage have symptoms of weakness,
and paresthesias develop within hours of the insult. Lower extremity findings are more common than upper extremity findings. These patients have a good prognosis for partial or complete recovery. Delayed neurologic damage may present days to years after the insult. Clinical presentations include ascending paralysis, or transverse myelitis.\textsuperscript{38} Motor findings predominate. Sensory findings are also common and may be patchy and not match motor levels of impairment. Although recovery is reported, the prognosis is usually poor.\textsuperscript{37}

**Lightning Injury**

On initial presentation, two thirds of seriously injured lightning patients have \textit{keranoparalysis}, which is a unique temporary paralysis secondary to lightning strike. It is characterized by lower and sometimes upper extremities that are blue, mottled, cold, and pulseless. These findings are secondary to vascular spasm and sympathetic nervous system instability.\textsuperscript{39} Generally, this condition clears within a few hours, although some patients may be left with permanent paresis or paresthesias. Paraplegia, intracranial hemorrhages, seizures, and electroencephalographic changes occur after lightning injuries.\textsuperscript{31,32,39-42} Loss of consciousness for varying periods is common, and confusion and anterograde amnesia are almost universal findings. Peripheral nerve damage is also common, and recovery is usually poor.\textsuperscript{43,44} A lightning strike to the head can cause a visual cortex defect that results in complex visual hallucinations.\textsuperscript{45} A syndrome of delayed muscle atrophy caused by electrical injury of the nerves is described, even in the absence of cutaneous burns.\textsuperscript{46}

**Other Viscera**

**Electrical Injury**

Injury to the lungs may occur because of associated blunt trauma but is rare from electrical current, perhaps because air is a poor conductor. Injury to visceral organs is also rare, but damage to the pancreas, liver, small intestine, large intestine, bladder, and gallbladder is reported.\textsuperscript{47}

**Lightning Injury**

Pulmonary contusion and hemorrhage are seen with lightning injury.\textsuperscript{49} Blunt abdominal injuries occur rarely. None of the other intra-abdominal catastrophes commonly associated with high-voltage electrical injury, such as gallbladder necrosis or mesenteric thrombosis, are seen with lightning injury.

**Other Low-Voltage Injuries**

An accurate history is essential to ensure that an apparent low-voltage injury was not caused by the discharge from a capacitor (as in the repair of a television, microwave oven, or computer monitor) or other high-voltage source. Although burns from low-voltage sources are usually less severe than burns from high-voltage sources, patients still may complain of paresthesias for an extended period, experience cardiac dysrhythmias, or have cataracts develop if the shock occurs close to the face or head.

As law enforcement use of electromechanical disruption devices (Tasers) increases, more subjects exposed to the associated electrical current will be evaluated in emergency departments. These devices deliver brief pulses of electrical energy that incapacitate the target subject. Taser use was listed as a contributory cause of death in 4 of 37 autopsy reports from restraint-related deaths.\textsuperscript{48} The evaluation and treatment of people subdued with such devices should focus on wounds or retained fragments caused by the probes, secondary injuries associated with the induced fall, and the patient’s organic or psychiatric conditions that prompted the officers’ use of the device.

**Complications**

**Electrical Injury**

Cardiac arrest generally occurs only at the initial presentation or as a final event after a long and complicated hospital course. Many of the complications are similar to those of thermal burns and crush injuries, including myoglobinuria, infection, and clostridial myositis. The incidence of acute myoglobinuric renal failure has decreased since the widespread adoption of aggressive alkalized fluid resuscitation. Fasciotozies or carpal tunnel release may be necessary for treatment of a compartment syndrome. Tissue loss and major amputations are common with severe high-voltage injuries and result in the need for extensive rehabilitation.

Neurologic complications, such as loss of consciousness, peripheral nerve damage, and delayed spinal cord syndromes, may occur.\textsuperscript{17,38,44} Damage to the brain may result in a permanent seizure disorder. Long-term neuropsychiatric complications include depression, anxiety, inability to continue in the same profession, aggressive behavior, and suicide. Stress ulcers are the most common gastrointestinal complication after burn ileus. Abdominal injuries from ischemia, vascular damage, burns, or associated blunt trauma may initially be overlooked.\textsuperscript{12,47}

**Lightning Injury**

Complications of lightning injury fall into three categories: (1) those that could be reasonably predicted from the presenting signs, such as hearing loss from tympanic membrane rupture or paresthesias and paresis from neurologic damage; (2) long-term neurologic deficits similar to deficits associated with blunt head injury and chronic pain syndromes; and (3) iatrogenic complications that are secondary to overaggressive management.

In the past, patients with lightning injuries were often treated similarly to patients with high-voltage electrical injuries. These injuries, however, are distinctly different. The treatment of lightning victims seldom requires massive fluid resuscitation, fasciotozies for compartment syndromes, mannitol and furosemide diuretics, alkalinization of the urine, amputations, or large repeated debridements.\textsuperscript{17,31}

**DIFFERENTIAL CONSIDERATIONS**

**Electrical Injury**

Electrical injuries are historically self-evident except in bathtub accidents, instances when no burns occur, or foul play. The mechanism of burn injury is relevant; flash burns have a much better prognosis than arc or conductive burns. Alterations in consciousness or seizures can be caused by the electrical injury or result from an associated traumatic brain injury.

**Lightning Injury**

The differential diagnosis of lightning injury is more complex, often because the incident is unobserved. It includes many of the causes of unconsciousness, paralysis, or disorientation of unclear etiology. Evidence of a thunderstorm or a witness to
the lightning strike may not be available, particularly when victims are alone when injured. The presence of typical burn patterns, such as feathering, may be helpful.

### MANAGEMENT

#### Out-of-Hospital

##### Securing the Scene

When first reaching the scene, prehospital medical personnel should secure the area so that bystanders and rescuers do not sustain other injuries. For high-voltage incidents, the power source must be turned off. Although many approaches to achieving this goal are recommended, the safest approach is to involve the local power company in high-voltage accidents. Accidents involving discrete electrical sources that are disconnected easily through a circuit box or switch are easier to manage, although rescuers should still ensure that the power is off before approaching the victim. The use of electrical gloves by emergency medical service personnel is dangerous. A microscopic hole in a glove can result in an explosive injury to the hand, as thousands of volts from the circuit concentrate there to enter the glove.

Although a line may be on the ground and appear to be de-energized, it may have substantial current flowing from it to the ground, making the surrounding area dangerous. This ground current spreads out in a circle along and just below the surface of the ground. De-energized lines may be re-energized by automatic circuit reclosers resulting in surges of current.49 During lightning incidents, nonhospital medical personnel must be vigilant because lightning can strike the same place twice.

##### Triage Considerations

Field evaluation of patients may involve triage of multiple victims. Traditional rules of mass casualty triage do not apply to lightning victims. Cardiorespiratory arrest is the major cause of death in lightning injuries.37 In the absence of cardiopulmonary arrest, victims rarely die in the field. Triage of lightning victims should concentrate on victims who appear to be in cardiopulmonary arrest. When multiple victims are involved, the evaluation of victims who are breathing may be delayed because they are likely to survive the incident. Although intrinsic cardiac automaticity may ensue, the respiratory arrest caused by central nervous system injury often prevails. If the victim is adequately ventilated during the interval, perfusion may be maintained.

##### Initial Out-of-Hospital Resuscitation

Electrical injury victims may require a combination of cardiac and trauma care because they often have blunt injuries and burns and possible cardiac damage. Spinal immobilization is indicated whenever associated spinal trauma is suspected. Fractures and dislocations should be splinted, and burns should be covered with clean, dry dressings. All patients with conductive injury should receive a bolus of 20 mL/kg of isotonic fluid, and subsequent fluid management should be based on the patient’s vital signs and clinical status.

#### Emergency Department

##### Assessment

The history obtained from bystanders and the nonhospital medical personnel regarding the type of electrical source, duration of contact, or environmental factors is helpful. An electrical injury should be treated similarly to a crush injury, rather than a thermal burn, because of the large amount of tissue damage that is often present under normal-appearing skin. As a result, none of the formulas for intravenous fluids based on percentage of burned body surface area are reliable. Standard crystalloid resuscitation in anticipation of myoglobinuria should be maintained. Cardiac monitoring is indicated for severely injured patients and for patients who have the indications listed in Box 140-6.30 All patients with high-voltage injury and patients with low-voltage injury and cardiopulmonary complaints should have an electrocardiogram (ECG) and cardiac biomarker determinations. Although electrocardiographic changes and dysrhythmias are common with electrical injuries, anesthesia and surgical procedures performed in the first 48 hours of care can be accomplished without cardiac complications.50,51

Most lightning victims behave as though they have had electroconvulsive therapy, with confusion and anterograde amnesia for several days. If any altered mentation or neurologic deterioration occurs after an electrical injury, a computed tomography scan is indicated to assess for intracranial hemorrhage.17,42

Lightning victims who do not experience cardiopulmonary arrest at the time of the strike generally do well with supportive therapy. Patients who have cardiopulmonary arrest may have a poor prognosis, particularly if there is hypoxic brain damage.50,52

##### Ancillary Tests

#### Electrical Injury

Patients sustaining an electrical injury should receive cardiac monitoring in the emergency department and an ECG despite the source voltage. The following laboratory tests may be considered in patients with evidence of conductive injury or significant surface burns: complete blood count, electrolyte levels, serum myoglobin, blood urea nitrogen, serum creatinine, and urinalysis. Patients with severe electrical injury or suspected intra-abdominal injury should also have pancreatic and hepatic enzymes measured and a coagulation profile obtained. If major debridements may be necessary, the emergency physician may consider ordering a type and crossmatch. Arterial blood gas analysis is indicated if the patient needs ventilatory intervention or alkalinization therapy. Patients should be evaluated for myoglobinuria, a common complication of high-voltage electrical injury. If the urine is pigmented or the dipstick examination of the urine is positive for blood, and no red blood cells are seen on microscopic analysis, the patient should be assumed to have myoglobinuria.

Creatine kinase (CK) levels and isoenzyme analysis should be performed. Peak CK levels predict muscle injury, risk of amputation, and length of hospitalization; the clinical value of a single level in the acute setting is not established. Cardiac biomarkers should be interpreted with care when diagnosing myocardial infarction in the setting of electrical injury. The peak CK level is not indicative of myocardial damage in electrical injury because of the large amount of injured skeletal muscle cells, which can contain a 20 to 25% CK-MB fraction. CK-MB fractions, electrocardiographic changes, thallium studies, angiography, and echocardiography correlate poorly in acute myocardial infarction after electrical injury. Other cardiac biomarkers (e.g., troponin) are not well studied in electrical injury but may prove useful in determining myocardial injury.

Radiographs of the spine should be obtained if spinal injury is clinically suspected or when patients cannot be assessed adequately because of altered mentation or the presence of other painful injuries. Angiography is not routinely indicated to plan débridements or amputations.22 Technetium pyrophosphate scanning can be useful to detect areas of clinically unsuspected myonecrosis.30,36 “Hot spots” may reflect 20 to 80% viable muscle and should be followed clinically.36,53,54 CT or magnetic resonance imaging may be useful in the evaluation of associated trauma and is essential for evaluation of possible intracranial injuries.

Lightning Injury

In patients injured by lightning, an ECG should be obtained. Serum biomarkers for cardiac injury are indicated in patients with chest pain, abnormal ECGs, or altered mentation. The severity or nature of the injuries may require other laboratory studies. Radiographic studies, particularly cranial CT evaluation, may be indicated, depending on the patient’s level of consciousness at presentation and throughout the evaluation and treatment.

Specific Therapies

Rhabdomyolysis

Victims of electrical injury who have heme pigment in the urine usually have myoglobinuria. Alkalization of the urine increases the solubility of myoglobin in the urine, increasing the rate of clearance. Urine output should be maintained at 1 to 1.5 mL/kg/hr until all traces of myoglobin have cleared from the urine, while the blood is maintained at a pH of at least 7.45 using sodium bicarbonate. Furosemide or mannitol may be used to cause further diuresis. In contrast to high-voltage injuries, rhabdomyolysis is rare with lightning injuries.

Burn Wound Care

Cutaneous burns should be dressed with antibiotic dressings, such as sulfadiazine silver. Electrical burns are especially prone to tetanus, and patients should receive tetanus toxoid and tetanus immune globulin on the basis of their immunization history. Prophylactic administration of high-dose penicillin to prevent clostridial myonecrosis is controversial.

Extremity Injuries

Management of electrical injuries of the extremities entails surgical management, including early fasciectomy, carpal tunnel release, or amputation of an obviously nonviable extremity. Extremities should be splinted in a functional position to minimize edema and contracture formation. The hand should be splinted in 35- to 45-degree extension at the wrist, 80- to 90-degree flexion at the metacarpophalangeal joints, and almost full extension at the proximal and distal interphalangeal joints.

DISPOSITION

Electrical Injuries

Admission

Indications for admission for electrocardiographic monitoring after low-voltage exposure can be reassured and discharged without performing any ancillary tests.53 Patients with cutaneous burns or mild persistent symptoms can be discharged if they have a normal ECG and no urinary heme pigment. Outpatient referral is provided in the event that current symptoms persist or new symptoms (delayed cataracts, weakness, or parasthesias) develop.

Electrical injury during pregnancy from low-voltage sources may result in fetal demise. A prospective cohort study of electric shock in pregnancy suggested that electric shock usually does not pose a major fetal risk.56 Nevertheless, obstetric consultation is advisable for all pregnant patients reporting electrical injury, regardless of symptoms at the time of presentation. Placental abruption, the most common cause of fetal death after blunt trauma, may result from even minor trauma, such as may be associated with electrical injuries. Patients in the latter half of pregnancy should receive fetal monitoring if there has been even minor blunt trauma and be considered high-risk patients for the remainder of their pregnancy.53 First-trimester patients should be informed of the remote risk of spontaneous abortion and, if no other indications for admission exist, may be discharged with instructions for threatened miscarriage and close obstetric follow-up evaluation. The prognosis for fetal survival after lightning strike is most dependent on the extent of the mother’s injuries. Fetal demise occurs in 50% of cases reported in the literature.57

Pediatric patients with oral burns may be safely discharged if close adult care is ensured. There is no evidence that an isolated oral burn correlates with cardiac injury or myoglobinuria. In general, these patients require surgical and dental consultation for oral splinting, eventual débridement, and, occasionally, reconstructive surgery. After appropriate consultation, if hospitalization is not deemed necessary, the child’s parents should be warned about the possibility of delayed hemorrhage and receive instructions to apply direct pressure by pinching the bleeding site and to return immediately to the emergency department.

Lightning Injuries

Many of the signs of lightning injuries, such as lower extremity paralysis and mottling, confusion, and amnesia, resolve with time. After spinal cord and intracranial processes are excluded, observation is the mainstay of treatment.

Consultation with other specialists may be indicated for otic and ophthalmic damage. More severely injured patients

Chapter 140 / Electrical and Lightning Injuries
require trauma surgeon and cardiologist consultations, although with lightning injuries medical pathology predominates. If there is a history of a loss of consciousness or if the patient exhibits confusion, hospital admission and observation are suggested. After evaluation, if the ECG is normal, asymptomatic patients (including patients with feathering burns) may be discharged home with referral for follow-up from an ophthalmologist and other specialists as indicated.

**KEY CONCEPTS**

- High-voltage electrical injury causes significant tissue and organ damage along the path between the entrance and exit wounds. As a result, victims are often more severely injured than they initially appear. Injury assessment must be detailed, fluid requirements during resuscitation are much greater than one would calculate from the surface burns alone, and extensive tissue débridement is often necessary.

- Victims of lightning injury may appear to have significant injuries, but symptoms (extremities that are cold and pulseless, mottled skin, paralysis, and confusion) usually resolve with time. After spinal cord and intracranial injuries are excluded, observation is the mainstay of treatment.

- Patients with low-voltage electrical injury who have only minor cutaneous burns or persistent minor symptoms may be discharged safely if they have a normal ECG and no urinary heme pigment.

CHAPTER 141

PERSPECTIVE

Underwater free diving (breath-holding) to salvage wrecks and to harvest seafood, sponges, coral, and mother-of-pearl has been practiced for more than 5000 years. Historic records indicate that the Persian King Xerxes employed a diver to recover sunken treasure in the fifth century BCE. Alexander the Great used divers to remove obstacles in the harbor of the city of Tyre in 332 BCE. Navies since the time of Alexander have used divers to construct defenses, sabotage enemy ships and harbor defenses, and salvage wrecks.

In an attempt to extend the duration of time underwater, some divers have used breathing tubes, such as hollow reeds; however, it is nearly impossible to use these at depths greater than 3 feet because of the underwater pressure restricting inspiration. Breathing bags (animal skins inflated with air) were also tried but made submersion impossible because of their buoyancy.

Shakespeare’s description of Clarence’s dream in King Richard III* (1597) may have been influenced by reports of the first diving bell (1531). Subsequent inventions, including diving dresses, from the 16th to the 19th centuries allowed divers to remain underwater for prolonged periods at depths of up to 12 fathoms (72 feet).† The first diving dress (1715) was a reinforced, leather-covered barrel with watertight arm-holes and a viewing porthole.‡

Colonel William Pasley, the officer in charge of a unit of the British Royal Engineers that salvaged the sunken warship HMS Royal George in 1840, observed symptoms in his divers: “Of the seasoned divers, not a man escaped the repeated attacks of rheumatism and cold.”§ At approximately the same time, similar symptoms and even fatalities were observed among caisson workers.∥ The ailment became known as caisson disease, but the construction workers on the Brooklyn Bridge (built from 1870 to 1883) attached the name “the bends” characterizing the symptoms that often caused the victim to bend forward in pain. The first clinical description of caisson disease was by Paul Bert in 1878. He correctly attributed the disease to nitrogen gas coming out of solution in the tissues during decompression. This led to the recommendation of slow ascents for pressurized workers and the development of the first recompression chambers.

Heavy diving helmets with surface-supplied air dominated underwater diving operations until the development of the self-contained underwater breathing apparatus (scuba). Scuba requires a demand regulator and high-pressure air tanks that allow the delivery of an air supply at an appropriate pressure for the depth of the diver. The significant breakthrough in making scuba possible was the invention of the Aqua-Lung by Jacques-Yves Cousteau and Emile Gagnan in 1943. The lighter and less expensive scuba equipment does not require a surface supply of air and the support personnel that are necessary for helmet diving.

The sport of scuba diving is increasingly popular. Since 1967, more than 10 million people have been certified as scuba divers. Worldwide, more than 500,000 new diver certifications are issued annually. The rate of mortality in diving varies between 1.5 and 9 per 100,000 dives. The vast majority of amateur divers use compressed air, open-circuit scuba equipment at depths less than 130 feet of seawater (fsw).

Systems that use artificial mixtures of various gases are employed to extend the depths to which divers can descend. Some of these are used in sport diving, but their use is uncommon and is primarily limited to commercial applications (Table 141-1).

Other variations of supplying air for divers are closed-circuit and semi-closed-circuit diving apparatus (“rebreathers”) that use calcium hydroxide, Ca(OH)₂, to absorb expired carbon dioxide. Oxygen is then added to the decarboxylated gas prior to rebreathing. The advantages of rebreathers over compressed air scuba are that they are more efficient (less gas is used for a given time), allow deeper dives and longer bottom times, and generate few, if any, bubbles.

PRINCIPLES OF DISEASE

Medical emergencies encountered by scuba divers include those common to environmental exposures (e.g., hypothermia, sunburn, and physical trauma), those common to aquatic activ-

sure and the volume of gas are inversely proportional \((PV = k)\). As pressure increases, the gas volume is reduced; as the pressure is reduced, the gas volume increases.

When working with Boyle’s law, the temperature of the gas is a constant value. However, temperature also affects the pressure and volume of a gas. Charles’ law describes the relationships of temperature and volume. At a constant pressure, the volume of a gas is directly proportional to the change in the absolute temperature \(\left(\frac{V_1}{T_1} = \frac{V_2}{T_2}\right)\). The general gas law \((P_1 \cdot V_1 \cdot T_1 = P_2 \cdot V_2 \cdot T_2)\) combines the laws to predict the behavior of a given quantity of gas when any of the factors change.

Dalton’s law states that the total pressure exerted by a mixture of gases is equal to the sum of the pressures (partial pressures) of the individual gases making up the mixture, with each gas acting as if it alone was present and occupied the total pressures of the individual gases making up the mixture, with the total volume \((P_{\text{total}} = P_1 + P_2 + P_3 + \ldots + P_n)\). Henry’s law states that the amount of any gas that dissolves in a liquid at a given temperature is directly proportional to the partial pressure of that gas. At higher ambient pressures, the concentration of each component of air in solution with blood and tissues increases until a new steady-state concentration is achieved.

The gases in a diver’s breathing mixture are dissolved into the body in proportion to the partial pressure of each gas in the mixture. The quantity of a particular gas that becomes dissolved is also governed by the length of time the diver is breathing the gas at the increased pressure and the inherent solubility of the gas. The dissolved gas in a diver’s body, regardless of quantity, depth, or pressure, remains in solution as long as the pressure is maintained. As the diver ascends, however, increasingly more of the dissolved gases come out of the solution and may form microbubbles in the circulation. A rapid ascent may reduce the pressure at a rate higher than the body can accommodate, and the bubbles (particularly nitrogen) may accumulate and disrupt body tissues and systems to produce decompression sickness (DCS). This is similar to the way that rapidly opening a bottle of soda allows bubbles of carbon dioxide to come out of solution rapidly.

If the ascent rate is controlled (i.e., through the use of the safe decompression tables or submersible dive computers), the gas is carried to the lung vascular bed and is exhaled before it accumulates to form significantly large or numerous bubbles in the tissues, similar to how opening a soda bottle slowly reduces the bubbling of the contained carbonated liquid.

Barotrauma, or injury caused by pressure changes, results when a diver is unable to equalize the pressure within air-filled structures to the ambient pressure of the environment during ascent or descent. The fractional changes in volume are greater near the surface. Thus, the greatest risk for barotrauma is in shallow water, where the proportional pressure changes are also the greatest.

**CLINICAL FEATURES**

**Middle Ear Barotrauma**

Middle ear barotrauma (MEBT), also known as barotitis or “ear squeeze,” is the most common complaint of scuba divers. It is experienced by 30% of novice scuba divers and 10% of experienced divers. The middle ear is an air-filled space with solid bony walls except for the tympanic membrane (Fig. 141-6). The eustachian tube is the only anatomic passage to the external environment.

As the diver descends, the water exerts increasing pressure against the intact tympanic membrane (TM). In normal circumstances, the diver performs various maneuvers to force air into the middle ear through the eustachian tubes, maintaining an equal pressure across the TM. If equilibration of middle ear pressure does not occur, the floppy medial third of the eustachian tube collapses shut, making any further attempts at equalization futile. Further pressure increases can cause the TM to rupture. The pain may or may not resolve as the TM ruptures. The ruptured TM, however, exposes the middle ear to cold water, inducing a transient nystagmus and vertigo secondary to caloric stimulation. In certain individuals, in whom the seventh cranial nerve passes unexposed through the middle ear, a facial palsy may occur.

**External Ear Barotrauma**

External ear barotrauma is less common than MEBT and results from the outward bulging of the TM during descent. Normally, the external auditory canal is filled with water during descent. If, however, air becomes trapped in the external auditory canal because of obstruction from cerumen, stenosis, earplugs, or a tight-fitting wet suit hood, a relative negative pressure develops in the external canal resulting in local pain.

**Inner Ear Barotrauma**

Inner ear barotrauma (IEBT) results in damage to the cochleovestibular apparatus. It is much less common than MEBT but is associated with greater morbidity. Initially, the mechanism of damage is similar to that of MEBT in that a large negative pressure gradient develops in the middle ear if the diver is unable to equalize pressure during descent. Inward deflection of the TM is transmitted to the oval window of the cochlea through the ossicles. Movement of the oval window creates a pressure wave within the perilymph of the cochlea, which causes an outward distention of the round window into the middle ear. Sudden equilibration of pressure in the middle ear or a vigorous Valsalva maneuver may rupture the round window. Two other pathologic changes may not be associated with frank rupture of the round window: hemorrhage into...
the inner ear and tearing of the labyrinthine (Reissner’s) membrane.

Symptoms associated with IEBT include variable hearing loss, severe vertigo, nausea, tinnitus, and fullness in the affected ear. Signs include severe nystagmus, positional vertigo, ataxia, and vomiting. The degree of sensorineural hearing loss is variable.

The history and physical examination are probably as sensitive as operative visualization of IEBT. The (Hennebert) fistula test may help. To perform this test, an insufflator and otoscope are used to compress and decompress air sequentially in the auditory canal. If nystagmus or vertigo is induced, the test suggests a perilymphatic fistula. Audiogram and tympanometric testing can provide objective data regarding the severity of sensorineural hearing loss and can detect concomitant conductive hearing loss. Distinguishing IEBT from inner ear DCS (a type of DCS II) can be challenging; if the diagnosis is in doubt, the patient should be treated as DCS II.

**Barosinusitis**

The air-filled maxillary, frontal, and ethmoidal sinuses are all susceptible to volume-pressure changes. Equilibration of pressure within the paranasal sinuses requires patent nasal passages. Obstruction by mucosal thickening, polyps, pus, or a deviated septum predisposes to sinus barotrauma. Pain is felt over the ethmoid, frontal, or maxillary sinuses during descent or ascent. The most commonly affected is the frontal sinus secondary to the relatively long and tortuous connection to the nasal passage. Epistaxis is common in barosinusitis.

**Facial Barotrauma**

Facial barotrauma results from negative pressure generation within the “artificial” airspace created by a dive mask over the eyes and nose. As water pressure increases during descent, a negative pressure develops within the mask, which must be equalized by forced exhalation through the nose. When this is not adequately performed, the large negative pressure gradient produces facial and conjunctival edema, diffuse petechial hemorrhages on the face, and subconjunctival hemorrhages. Rarely, optic nerve damage can result from severe facial barotrauma.

**Temporomandibular Joint Dysfunction**

Temporomandibular joint dysfunction can be seen in divers who experience teeth clenching and poor occlusion because of a poorly fitting regulator mouthpiece. The pain associated with this condition is typically felt in the region of the ear and can be mistaken for MEBT. Customized mouthpieces are available to relieve the problem.

**Nitrogen Narcosis**

Nitrogen narcosis, known as “rapture of the deep,” results from the intoxicating effects of increased tissue nitrogen concentration at depth. Symptoms include euphoria, a false feeling of well-being, confusion, loss of judgment or skill, disorientation, inappropriate laughter, diminished motor control, and tingling and vague numbness of the lips, gums, and legs. When breathing compressed air, symptoms typically begin to occur at approximately 100 feet and often become profound at depths greater than 150 feet. There is a large degree of individual variability in susceptibility to nitrogen narcosis. Although the effects of nitrogen narcosis resolve with ascent to shallower depths, the diver may drown because of poor judgment or seriously impaired motor skills in the presence of a dive emergency. Because of the dangers of breathing nitrogen at increased partial pressures, the use of compressed air is not recommended for sport diving to depths greater than 120 feet.

**Oxygen Toxicity**

At elevated partial pressures for extended periods of time, oxygen can be toxic to the central nervous system (CNS) or lungs. Oxygen becomes toxic to the CNS when its partial pressure exceeds 1.6 ATA. Oxygen partial pressures less than 1.4 ATA are unlikely to produce CNS toxicity. Symptoms of CNS oxygen toxicity may be remembered by the mnemonic VENTIDC:

V: Visual symptoms (tunnel vision or blurred vision)  
E: Ear symptoms (tinnitus)  
N: Nausea or spasmodic vomiting  
T: Twitching and tingling symptoms (small facial muscles, lips, or muscles of the extremities)  
I: Irritability, confusion, agitation, and anxiety  
D: Dizziness, clumsiness, incoordination, and unusual fatigue  
C: Convulsions

Deep divers prevent oxygen toxicity by breathing mixed gases with decreased oxygen content (e.g., hypoxic Trimix). Breathing oxygen-enriched mixtures at depth makes a diver more susceptible to oxygen toxicity.

Pulmonary oxygen toxicity (low-pressure oxygen poisoning) can occur after 24 hours of exposure to partial pressures of oxygen in excess of 0.6 ATA. The symptoms of pulmonary oxygen toxicity include a burning sensation or pain on inspiration and coughing. Pulmonary function gradually becomes normal after the exposure is terminated, but pneumonitis and permanent fibrosis are possible.

**Contaminated Air**

Rarely, other gases, such as carbon monoxide and carbon dioxide, can contaminate the air that is compressed into a tank. This can happen, for example, if the compressor intake is placed too close to the compressor’s engine exhaust. As in the case of oxygen and nitrogen, the partial pressure of these contaminants in the tissues increases dramatically with depth, potentiating their clinical effects. The symptoms of hypercarbia or carbon monoxide poisoning are more severe at elevated partial pressures. Hypercarbia increases a diver’s susceptibility to CNS oxygen toxicity.

Rebreathers release microscopic calcium hydroxide or “soda lime” dust particles into the apparatus. These particles are small enough and have geometric characteristics that allow them to be deposited in the alveoli. When soda lime comes

*A diver breathing compressed air would attain a partial pressure of 1.6 ATA of oxygen at a depth of 218 fsw. This far exceeds the depth to which sport divers would go. Treatment in a hyperbaric chamber with 100% oxygen attains this partial pressure at only 20 fsw. Therefore, hyperbaric treatment combines alternating periods of delivering 100% oxygen and air.  
*A diver breathing compressed air would attain a partial pressure of 0.6 ATA of oxygen at a depth of 60 fsw. It is extremely unlikely that a sport diver would ever be exposed for the duration that is required to produce toxicity; however, long exposures to higher levels of oxygen, such as administered according to Recompression Treatment Tables 4, 7, and 8, may lead to pulmonary oxygen toxicity.*
into contact with water, it forms a caustic liquid. In the event of a hose rupture allowing seawater contamination of the circuit, caustic burns to the mouth, throat, and airways may result. Chronic exposure to soda lime dust may contribute to long-term effects on respiratory function.

### Decompression Sickness

The term *decompression sickness* refers to a spectrum of clinical illnesses that result from the formation of small bubbles of nitrogen gas in the blood and tissues.\(^7,8\) The clinical expression of DCS depends on the location, destination, and degree of nitrogen bubble formation in blood and tissues. Small, asymptomatic venous gas emboli are common in the ascending diver and are filtered by the lungs without apparent permanent damage.\(^9,10\) Persistent intravascular bubbles, however, elicit inflammatory cascades, cytokines, the complement system, platelet aggregation, and thrombosis.\(^11\) Furthermore, the bubbles can cause mechanical obstruction, ischemia, and tissue hypoxia. Nitrogen is highly fat soluble, and the heavily myelinated white matter of the CNS is at particular risk for DCS.

The incidence of DCS is estimated to be 2.8 cases per 10,000 dives.\(^12\) The potential for development of DCS increases with the length and depth of a dive. Other risk factors include age, obesity, fatigue, heavy exertion, dehydration, fever, cold ambient temperatures after diving, diving at high altitude, and flying after diving. Tobacco and ethanol use may also increase susceptibility to DCS. The risk of DCS is 2.6 times greater for men than women.\(^13\) This difference is possibly due to risk-taking behaviors. There appears to be no increase in DCS in women who are taking oral contraceptive agents or menstruating during diving.

A patent foramen ovale (PFO) may be a risk factor for increased susceptibility to DCS. Sixty-five percent of divers who present with serious DCS have a PFO.\(^14\) Reul and colleagues\(^15\) report brain lesions in 27% of sport divers. This percentage is roughly the same as the prevalence of PFO or other right-to-left shunts in the general population. These multiple brain lesions may be caused by bubbles in the venous circulation that are not filtered by the vasculature of the lungs but enter the arterial circulation, even in the absence of other DCS symptoms.\(^16\) Most sport divers do not undergo screening for PFO with echocardiographic bubble studies, and there is reason to believe that some PFOs may open only at increased ambient pressures so that bubble studies are negative if conducted at 1 ATA.\(^17\)

The U.S. Navy dive tables estimate the amount of nitrogen that accumulates in the body during a dive to a particular depth for a specific duration.\(^3\) The tables calculate a maximal dive time, called the “no-decompression limit,” which represents the amount of time a diver may spend at a maximum depth and return to the surface without sufficiently exceeding the solubility of nitrogen at sea level to produce DCS. The diver still must ascend in a slow, controlled manner to allow the gradual release of nitrogen. Off-gassing continues after the diver has surfaced; it takes up to 12 hours at the surface for nitrogen stores to return to normal sea level values. Repetitive dives within several hours result in accumulation of tissue nitrogen and shorter no-decompression limits. Because dive tables are based on several assumptions regarding N₂ elimination, even strict adherence to these tables does not ensure that DCS will not occur.\(^3\)

If the no-decompression limits are exceeded, underwater decompression stops are recommended. The depth and duration of these stops can be derived from the U.S. Navy Standard Air Decompression Dive Tables.\(^3\)

Many sport scuba divers use submersible dive computers to calculate maximum dive times. These computers use mathematical algorithms to model nitrogen saturation in human tissues. Although they remove human calculation errors, such computers also tend to extend no-decompression times to their maximum limits. It is important to realize that divers can develop DCS even when within the no-decompression limits whether calculated by computer or derived from a dive table.

The clinical manifestations of DCS are divided into two categories—type I and type II. Type I DCS affects the musculoskeletal system, skin, and lymphatic vessels. Type II DCS involves any other organ system. Type II DCS is more commonly reported and more serious than type I (this may indicate recognition and reporting bias more than the actual incidences).

Type I DCS is also called the bends. It is experienced as variable and periairterial pain in the arms and legs. The elbow and shoulder joints are most commonly affected. Local tenderness and erythema are uncommon. Classically, the placement and inflation of a blood pressure cuff to 150 to 200 mm Hg on an affected joint produces relief of pain and helps confirm the diagnosis; however, the sensitivity of this maneuver was as low as 61% in one study.\(^18\) Skin manifestations of type I DCS may include pruritus (niggles), erythema, and marbling. Pruritus without other signs, however, usually occurs only during decompression in hyperbaric chamber workers as a result of nitrogen diffusing through the skin; it is not considered a true form of DCS and is rare in scuba divers. Skin marbling, known as cutis marmorata (patchy cyanotic marbling of the skin), is a true form of DCS and results from venous stasis. It may begin as severe pruritus and progress into an erythematous rash and then to skin mottling. Cutis marmorata does not follow a dermatomal distribution and commonly involves the trunk and torso. Lymphatic obstruction by air bubbles can also occur, causing extremity edema.

Type II DCS includes symptoms beyond those described for type I DCS. These symptoms can involve the CNS, the inner ear, and the lungs. The CNS is particularly susceptible to decompression illness because of its high lipid content. The spinal cord, especially the upper lumbar area, is more often involved than cerebral tissue. Symptoms of spinal DCS include limb weakness or paralysis, paresthesias, numbness, and low back and abdominal pain. Limb symptoms often begin as a distal prickly sensation that advances proximally, followed by progressive sensory or motor loss. A dermatome sensory level occurs in some spinal DCS patients, often at the T12 to L1 dermatomes. Bladder symptoms, fecal incontinence, and priapism may occur. Unlike patients with spinal cord trauma, patients experiencing DCS may have patchy or unequally distributed sensory and motor findings.

Spinal DCS can occur alone or in combination with cerebral, inner ear, or pulmonary symptoms. Cerebral symptoms include mild to moderate headache, blurred vision, diplopia, dysarthria, unusual fatigue, inappropriate behavior, and a sense of detachment. Loss of consciousness in CNS DCS is rare (in marked contrast to the presentation in arterial gas embolism [AGE]).\(^19\) Magnetic resonance imaging, computed tomography (CT), and single photon emission CT using technetium 99m-labeled hexamethylpropyleneamine can identify the bubbles of CNS DCS. However, no imaging studies are sensitive enough to exclude DCS, and the use of imaging should not delay transfer for definitive therapy.

Inner ear DCS is commonly called “the staggers.” The symptoms of inner ear DCS are the same as those of IEBT and include nausea, dizziness, vertigo, and nystagmus.
Pulmonary DCs is called “the chokes.” All divers are exposed to some degree of microbubble emboli to the lungs on ascent. The progression to symptoms probably depends on the number and volume of bubbles. The deposition of venous gas emboli in the pulmonary arterial circulation produces progressive dyspnea, cough, and chest pain. The cough may progress to paroxysmal fits with worsening pain.

The physical examination of patients suffering from pulmonary DCs may reveal cyanosis and hypotension in association with increased central venous pressure and pulmonary arterial pressure, right-sided strain on an electrocardiogram, and a decreased end-tidal CO2 level. The condition may progress to respiratory arrest. Ancillary tests for pulmonary DCs not only are insensitive but also lead to unnecessary delays in treatment. Even after ascent from very shallow saturation dives, microbubbles in the venous circulation can be routinely detected by M-mode ultrasonography; however, their presence does not necessarily correlate with symptoms.

DCS may be particularly dangerous to a developing fetus in the womb of a scuba diving mother because the majority of the fetal circulation bypasses the pulmonary bed through the foramen ovale and the ductus arteriosus. This bypass prevents the fetal lungs from acting as a filter for microbubbles. In addition, venous gas emboli may appear in the fetal circulation before they are apparent in the maternal circulation. Human data on the effects of diving on pregnant women suggest a higher incidence of low-birth-weight infants, prematurity, congenital malformations, stillbirths, and spontaneous abortions. There are no safe-diving tables that would protect a fetus from DCS; therefore, pregnant women should be advised to refrain from scuba diving.

Pulmonary Barotrauma

Without continuously expiring on ascent, a scuba diver who takes a full breath at 33 fsw will have twice the lung volume at the surface (Boyle’s law). Because the volume expansion of the alveoli is limited, the increase in pressure either forces gas bubbles across the alveolar-capillary membrane or causes the wall of the alveoli to rupture. A differential pressure of only 80 mm Hg between the alveoli and chest wall, corresponding to a change in depth of 3 to 4 feet, is all that is required to force air bubbles across the alveolar-capillary membrane. The greatest risk for pulmonary barotrauma occurs in less than 10 feet of water. Pulmonary barotrauma can result in the following five conditions: AGE, pneumothorax, pneumomediastinum, subcutaneous emphysema, and alveolar hemorrhage.

Risk factors sought from the dive and medical history may suggest the diagnosis of pulmonary barotrauma. In most cases, fast ascent, panic, problems regulating buoyancy, or running out of air is noted.

Scuba divers who suffer from asthma probably have a twofold increased risk for a dive accident compared with the general diver population. There are six mechanisms by which asthmatics are at higher risk for pulmonary barotrauma:

1. Bronchospasm and mucus plugging predispose local regions of lung to injury.
2. When air is compressed, it becomes denser. This may contribute to greater turbulent flow through narrow airways.
3. During scuba diving, there is a reduction in breathing capacity related to the effects of immersion. At 33 feet underwater, the maximum breathing capacity of a normal scuba diver is only 70% of the surface value. At 100 feet underwater, the reduction is approximately 50%.
4. When compressed air (from the scuba tank) expands in the regulator before delivery to the lungs, it cools (Charles’ law). Breathing chilled air may trigger bronchospasm in asthmatics who have a cold-induced component of their disease.
5. Scuba diving takes some effort; asthmatics who have an exercise-induced component of their disease may experience bronchospasm.
6. Compressed air may be contaminated by pollen and other allergens.

Traditionally, asthmatics are advised not to dive. However, a consensus of experts at a 1995 Undersea and Hyperbaric Medical Society workshop proposed more liberal guidelines. The risk of diving is probably acceptable if the diving candidate with some asthmatic history demonstrates normal pulmonary function at rest (forced vital capacity [FVC], mid-expiratory flow, forced expiratory volume in 1 second, and forced expiratory flow between 25 and 75% of FVC) and after strenuous exercise. Asthma severity can wax and wane. Because symptoms may worsen for 4 to 6 weeks after an upper respiratory infection or during certain seasons, an asthmatic should refrain from diving until completely free of symptoms despite the pulmonary function criteria.

Arterial Gas Embolism

The most severe form of pulmonary barotrauma is AGE. It is the second leading cause of mortality among sport divers after drowning, accounting for approximately 30% of diving-related deaths. Typically, it results when air bubbles are forced across the alveolar-capillary membrane, escape into the pulmonary venous circulation, and proceed through the left atrium and ventricle into the arterial circulation. Clinical symptoms and signs are in part the result of mechanical obstruction by gas bubbles. AGE can also result from a right-to-left shunt of venous bubbles, such as in a diver with a PFO.

Although air bubbles may embolize to any organ, the coronary and cerebral arteries are associated with the most serious consequences. Emboli to the coronary arteries may cause cardiac ischemia, myocardial infarction, dysrhythmias, or cardiac arrest. Dysrhythmias are also indirectly caused by centrally mediated autonomic dysfunction from cerebral emboli. Mechanical occlusion of the cerebral vasculature from emboli, most commonly to the anterior and middle cerebral arteries, causes a variety of symptoms and signs similar in appearance to an acute stroke.

The clinical manifestations of AGE may be sudden, dramatic, and life-threatening. Divers who have supposedly “drowned” may actually have lost consciousness during ascent as a result of cerebral gas emboli. Any diver who has breathed compressed air at any depth underwater and who surfaces unconscious or who loses consciousness within 10 minutes of reaching the surface should be assumed to be suffering from AGE. The most common presentation of AGE includes a global alteration of consciousness, headache, dizziness, convulsions, and visual changes. Other common presenting symptoms and signs include cranial nerve symptoms, unilateral weakness, unilateral or bilateral sensory loss, ataxia, and speech changes. Pulmonary symptoms, including dyspnea, pleuritic chest pain, and hemoptyis, occur in 25 to 50% of cases.

Pneumothorax

When the air that escapes from alveoli as a result of pulmonary barotrauma crosses the visceral pleura, it may result in a pneumothorax. A tension pneumothorax is a rare complication.
The symptoms and signs of a pulmonary barotrauma-related pneumothorax are typical for a pneumothorax of any cause. Pulmonary barotrauma can also cause alveolar hemorrhage. Hemoptysis is coincident with chest pain and dyspnea.

### Pneumomediastinum and Subcutaneous Emphysema

Pneumomediastinum results when air crosses the alveolar endothelium and dissests into the pulmonary interstitium. Most commonly, the air then travels into the neck, mediastinum, or pericardium. The manifestations of pneumomediastinum may include fullness in the neck, palpable subcutaneous crepitation, and a change in voice quality or timbre. Unless evidence of either hemodynamic instability or airway compromise exists, interstitial air or subcutaneous emphysema is not a life-threatening condition.

### Alternobaric Vertigo

Alternobaric vertigo (ABV) results from an inability to equalize pressure within the middle ear during ascent. Although equalization during descent requires active maneuvers to maintain eustachian tube patency, air normally exits the middle ear without difficulty during ascent because the pressure within the middle ear exceeds ambient pressure. In the setting of mucosal edema or thickening within the eustachian tube, however, the passage of air may be impeded. The problem is typically unilateral. When the pressure gradient within the middle ear reaches 60 cm H2O, increased labyrinthine discharge produces nystagmus, with the fast phase toward the affected ear. Clinically, the patient experiences a profound but transient sense of vertigo during ascent that may be associated with nausea and vomiting. Unlike those of IEBT, the symptoms are self-limited.

### Barodontalgia

Occasionally, air that is trapped beneath a poorly filled dental cavity expands on ascent, leading to dental pain. This condition is relatively benign and self-limited.

### Gastrointestinal Barotrauma

Serious gastrointestinal barotrauma is a rare condition in scuba divers. It results from the expansion of bowel gas in the small intestine and colon on ascent after diving. Predisposing factors include consumption of carbonated beverages, large meals, or gas-producing foods before diving as well as performing the Valsalva maneuver in the head-down position. Symptoms include eructation, flatulence, bloating, and crampy abdominal pain. In divers with inguinal or other hernias, the potential for expansion of trapped gas within the hernia exists, and expansion may result in incarceration or strangulation. Gastric rupture is a rare complication. Although gastrointestinal barotrauma is a rare entity, it must be suspected in the diver-patient with a provocative history and abdominal pain.

### Pulmonary Edema

Pulmonary edema while scuba diving was first reported in 1981. An increase in afterload (from vascular hyper-reactivity, possibly triggered by cold) combined with an increase in preload (from the hyperbaric underwater environment) may be the cause.

---

**BOX 141-1 FOCUSED DIVE HISTORY**

When was the first onset of symptoms?  
What type of equipment was used? Compressed air, mixed gas, enriched air, rebreather? What was the source of the gas?  
Did the dive approach or exceed decompression limits?  
Was a dive computer used?  
What were the number, depth, bottom time, total time, and surface intervals for all dives in the 72 hours preceding symptoms (the dive “profiles”?  
Were decompression stops used? Was in-water decompression attempted?  
What was the time delay from the last dive to air travel?  
Did the diver experience difficulty with ear or sinus equilibration? Did the pain occur on descent or ascent?  
Was the diver intoxicated? Dehydrated? Working strenuously?  
How long after the dive did symptoms present? Were they present at surfacing? Delayed? Progressive?  
Is a medical history of ear or sinus infections or abnormalities present? Emphysema or asthma? Coronary artery disease? Patent foramen ovale? Neurologic illness?

---

**DIAGNOSTIC STRATEGIES**

Focused questions concerning the dive profile, including the depth and length of the dive and a careful assessment of when the symptoms first occurred, may provide important diagnostic clues (Box 141-1). A physician unfamiliar with the specifics of scuba diving may rely on the assessment of members of the dive group to determine whether maximum dive limits were approached. When making the diagnosis of a dive injury, it is helpful to think of the injuries in terms of occurring during descent, while at depth, or during ascent (Fig. 141-7).

The diagnosis of MEBT can be established by history and physical examination alone (Table 141-3). Symptoms include ear pain during descent, transient vertigo, and hearing loss. A grading system for MEBT based on symptoms and signs is useful in selecting treatment regimens (Table 141-4). Other signs may include conductive hearing loss and, occasionally, unilateral facial paralysis.

**DIFFERENTIAL CONSIDERATIONS**

Most diving injuries have limited differential diagnoses that include medical disorders and trauma unrelated to dysbarism. The differential diagnosis of IEBT includes inner ear DCS, ABV, and isolated MEBT with a rupture of the TM. It is relatively easy to distinguish IEBT from MEBT and ABV because the vestibular symptoms associated with the latter two entities are transient and self-limited. When IEBT occurs simultaneously with MEBT, the presence of both may be documented by an audiogram, which demonstrates both a conductive and a sensorineural hearing loss.

The differentiation of IEBT from inner ear neurologic DCS is crucial, particularly because the treatments differ. A careful history is the most important tool in diagnosis. An IEBT is more likely when symptoms begin during descent or the diver relates a history of difficulty equilibrating or performing a vigorous Valsalva maneuver. If the dive profile is examined and the no-decompression limits are approached or exceeded and symptoms began soon after surfacing, inner ear DCS is more likely.
The differentiation of inner ear DCS from barotrauma is based on the history, particularly the time of onset of symp-
toms. A history of difficulty equalizing the ears on descent, or
the onset of symptoms early in the dive, suggests barotrauma.
A history of a dive that approaches decompression limits, or
the onset of symptoms during or soon after ascent, and the
presence of other neurologic findings suggest DCS. A trial of
recompression therapy is indicated if concern about DCS
exists.

The differential diagnosis of pulmonary DCS includes AGE (Table 141-5). Although the treatment of both requires recom-
pression therapy, attempts should be made to distinguish the

two forms of injury. Almost all cases of AGE present within the first 10 minutes of surfacing, whereas DCS presents more typically after 10 minutes: 42% of pulmonary DCS symptoms begin within 1 hour of surfacing, 60% within 3 hours, 83% within 8 hours, and 98% within 24 hours.3

MANAGEMENT

Several invaluable resources are available for advice on the management of diving accidents. The Divers Alert Network (DAN), located at Duke University in Durham, North Carolina, is a membership association that provides courses on diving-related emergencies and publishes data on diving accidents and fatalities. Clinicians can locate the nearest hyperbaric chamber by calling DAN. DAN provides a 24-hour medical emergency hotline at 919-684-8111 and a nonemergency advisory line Monday through Friday, 9 am to 5 pm Eastern time, at 919-684-2948. DAN also maintains a website with links to key information at http://www.diversalertnetwork.org. DAN uses a telephone intake form, the “DAN On-Site Neurological Assessment for Diver’s History” (Fig. 141-8); familiarity with this form may enhance the emergency physician’s communications with DAN.

The U.S. Navy has made available its most current diving manual (revision 5) at its website, http://www.supsalv.org/pdf/Diveman.pdf. It contains a wealth of information about diving...
principles, equipment, and operations. It also has extensive information on diving medicine and recompression chamber operations.

**Diving Disorders Requiring Recompression Therapy (Box 141-2)**

Immediate treatment should include the administration of 100% oxygen. This reduces the bubble size by increasing the differential pressure for nitrogen diffusion out of the bubbles and speeds the washout of nitrogen from the tissues.\(^\text{40}\) Recompression is the only definitive treatment for DCS (types I and II) and AGE. Treatment of DCS or AGE should not be withheld even if a significant time delay in transfer to a hyperbaric chamber is unavoidable. In-water recompression is risky, demanding, time-consuming, and not typically recommended.

Hyperbaric therapy for AGE should be initiated as soon as possible for optimal results, but there are cases of significant improvement even in the face of long delays until recompression.\(^\text{41}\) Patients with AGE who are recompressed within 5 minutes of surfacing have a mortality rate of 5%, and there is an extremely low risk of morbidity among the survivors.\(^\text{17}\) If recompression is delayed by 5 hours or more, the mortality rate increases to 10%, with 50% morbidity.\(^\text{17}\) Although spontaneous resolution of symptoms may occur in patients with AGE, all patients should be recompressed. One rationale for this approach is that although microbubbles may clear from the cerebral circulation, secondary capillary edema and swelling may result in a delayed recurrence of symptoms. Furthermore, more subtle symptoms may be appreciated only after the resolution of more prominent ones. Finally, minor symptoms may progress, and the relapse rate is high in untreated cases.

Similarly, the prognosis for DCS when treated with recompression is generally good but depends on the severity of symptoms at onset and the delay to recompression. A delay to definitive recompression treatment is associated with a worse outcome in cases of severe DCS. Patients can obtain some benefit from recompression, however, even if treatment is initiated more than 24 hours after the dive. Recompression therapy for DCS may be initiated as late as 10 to 14 days after exposure if necessary.\(^\text{42}\)

Monoplace hyperbaric chambers are compact, lightweight, and more widely available than multiplace chambers. Unfortunately, because of their design, most cannot be pressurized beyond 3 ATA (100 fsw) or deliver air-oxygen mixtures. Recompression therapy is usually performed based on U.S. Navy Treatment Tables (Fig. 141-9; Table 141-6). The 3 ATA limit renders some of the U.S. Navy Treatment Tables unsuitable for monoplace chambers. The small size of a monoplace chamber also prevents the unstable patient from receiving attendance within the chamber. The decision to bypass a monoplace chamber for a potentially more distant multiplace hyperbaric chamber must be weighed carefully in consultation with a hyperbaric specialist. The DAN hotline may be helpful in locating the closest suitable chamber.

**BOX 141-2 Diving Disorders That Require Recompression Therapy**

- Decompression sickness (DCS) type I
- DCS type II
- Arterial gas embolism
- Contaminated air (carbon monoxide poisoning)

---

**Figure 141-9.** Treatment of arterial gas embolism or serious decompression sickness. (Modified from Figure 20-1 from Naval Sea Systems Command: U.S. Navy Diving Manual, revision 5. Published by direction of Commander of Naval Sea Systems, United States Navy, August 2005: Treatment of Arterial Gas Embolism or Serious Decompression Sickness.)
Ground transport to a hyperbaric facility is preferred over air transportation, if feasible, because an increase in altitude lowers the ambient pressure and allows microbubbles to expand. If air transportation must be used, it is important to maintain cabin pressure at less than 1000 feet. Commercial aircraft are typically pressurized to a cabin altitude of 5000 to 8000 feet in cruise flight (>30,000 feet). Most of these aircraft are capable of near-sea level cabin pressures if flying no higher than 20,000 to 25,000 feet. Because helicopters are not pressurized, it is recommended that they maintain an altitude of no more than 500 feet above the departure facility. The transferring physician can also consider transportation of the patient in a portable, monoplace chamber, if one is available.

The goals of recompression therapy are to reduce the mechanical obstruction of air bubbles, to facilitate the washout of nitrogen by increasing the tissue-blood nitrogen gradient, and to increase oxygen delivery to ischemic tissue. It is generally accepted that hyperbaric oxygen treatment is superior to hyperbaric air treatment for DCS and AGE. The selection of a treatment protocol for a particular patient, however, is best made by a qualified hyperbaricist. The U.S. Navy

*The times required listed in this table for the various treatment regimens do not include the time required for descent.

AGE, arterial gas embolism; DCS, decompression sickness.

Treatment Tables are one of several widely accepted sets of treatment protocols. Patients suffering from DCS type I should be treated with recompression; the clinician should also search for symptoms of the more severe manifestations of DCS.

In addition to recompression therapy, several adjunctive treatments are advocated in the treatment of DCS and AGE. One hundred percent oxygen administered before recompression may facilitate the washout of inert gases. Intravenous fluid administration to ensure a urine output of 1 or 2 mL/kg/hr may facilitate tissue perfusion and washout of inert gases. The treatment or prevention of hypothermia may also help perfusion and off-gassing.

There are no medications that prevent or lessen the symptoms of DCS or AGE. Aspirin therapy (325–650 mg) or other platelet inhibitors may impede platelet aggregation in DCS. Steroids have been advocated clinically for neurologic DCS and AGE; however, they have not been of benefit in animal studies and evidence implies that they may cause harm. Lidocaine therapy—possibly because it reduces the cerebral metabolic rate, preserves cerebral blood flow, or reduces leu-
kocyte adherence to damaged endothelium—may prove useful in the treatment of DCS.

Cardiac dysrhythmias may be refractory to standard treatments until the diver is recompressed. Seizures may be managed with benzodiazepines; however, mannitol should be avoided. Spinal DCS patients often develop urinary retention requiring bladder catheterization. Of note, endotracheal tube and urinary catheter balloons should be inflated with water or saline (not air) before initiating recompression therapy.

Transport of the patient with AGE in the supine position is recommended to maximize arterial-venous flow. The Trendelenburg position, once thought to reduce the degree of cerebral embolization, increases intracranial pressure, facilitates coronary gas embolization, and should be avoided.

There is limited experience with carbon monoxide poisoning from contaminated air supplies in a diving environment. This condition should be treated immediately with normobaric 100% oxygen and may require hyperbaric oxygen therapy.

### Diving Disorders Not Requiring Recompression Therapy (Box 141-3)

Prevention of MEBT requires that the diver equalize the pressure in both middle ears. Any diver who cannot clear both ears on the surface should not dive. The diver should never perform a forceful Valsalva maneuver during descent or ascent in order to clear the ears because of the risk of ABV, round or oval window rupture (descent), or pulmonary barotrauma (ascent). The prophylactic use of pseudoephedrine, 60 mg taken 30 minutes before diving, may reduce the incidence and severity of MEBT.46 The use of this medication to facilitate diving with symptoms of an upper respiratory infection, however, is not recommended. Antihistamines should be avoided before diving. Sinusitis and upper respiratory infections increase the likelihood of suffering barotitis. Diving should be avoided for 2 weeks after the resolution of an upper respiratory infection.

Treatment for uncomplicated serous otitis from MEBT includes topical nasal vasoconstrictors such as phenylephrine or oxymetazoline hydrochloride and repeated Frenzel maneuvers to displace the fluid through the eustachian tube. The Frenzel maneuver is performed by swallowing with a closed glottis, pursed lips, and pinched nose. If the physical examination reveals a ruptured TM, prophylactic treatment should also include an oral antibiotic. Oral steroids may speed recovery when a seventh nerve palsy is diagnosed in conjunction with a perforated TM, although this disorder is typically self-limited. Diving must also be suspended until the TM heals to prevent calorically induced vertigo.

Treatment of external ear barotrauma includes cleaning the external canal and removing foreign bodies. Earplugs should never be worn when diving.

A conservative treatment approach to IEBT includes bed rest for 5 to 7 days with the head elevated, avoidance of straining and the Valsalva maneuver, and decongestants to facilitate drainage of the middle ear. Early surgical intervention may benefit patients with total or near-total hearing loss but not isolated high-frequency hearing loss. All patients with IEBT should be provided referral to an otolaryngologist because IEBT suggests significant injury to the cochleovestibular system.

Treatment of barosinusitis is typically conservative, including the use of decongestants and, occasionally, antibiotics. If symptoms persist, referral for antrostomy should be considered, particularly to prevent future recurrences. The patient should be advised not to dive until any underlying respiratory infection or acute inflammatory process has resolved completely.

The victim of facial barotrauma may have a dramatic appearance, but the condition is usually benign and requires no specific treatment. The patient should be advised not to resume diving until facial edema has resolved.

Nitrogen narcosis symptoms should resolve on surfacing when the partial pressure of nitrogen decreases. Seemingly persistent symptoms should prompt a search for other etiologies, such as DCS, cerebral AGE, contaminated air, and near drowning.

With the exception of AGE, none of the pulmonary barotrauma disorders (pneumothorax, pneumomediastinum, subcutaneous emphysema, and alveolar hemorrhage) requires recompression therapy. Treatment with 100% oxygen may aid in the resolution of the disorders. Although tube thoracostomy may not be required for the treatment of a small pneumothorax, such a tube should be placed if the diver is to undergo recompression therapy for concomitant AGE or DCS to prevent a tension pneumothorax. Catheter aspiration of the pneumothorax is an acceptable alternative to tube thoracostomy if the patient will not receive positive-pressure ventilation or recompression therapy.

The evaluation and management of pneumomediastinum includes serial chest radiographs to ensure that no coexisting pneumothorax develops and discharge with appropriate pain medication. One hundred percent oxygen therapy may hasten the resolution of symptoms. In the rare case of respiratory compromise, tracheal intubation may be required. Most important, the presence of interstitial pulmonary emphysema should alert the physician to the possible coexistence of more severe forms of pulmonary barotrauma. The need for a surgical decompressive treatment of subcutaneous emphysema alone is extremely unlikely. Supportive therapy to correct hypoxia is indicated in the treatment of alveolar hemorrhage.

Careful equalization during a slow ascent can prevent the occurrence of ABV. Oral and topical decongestants may be indicated if symptoms persist. Occasionally, myringotomy is required.

### DISPOSITION

Decompression tables are based on the premise that the diver returns to an ambient pressure of 1 atm on surfacing. A further reduction in ambient pressure, however, occurs either when ascending in altitude after diving or when diving at altitude. Commercial airliners may be pressurized to a cabin altitude of 5000 to 8000 feet in cruise flight. Many cases of DCS have a
delay in the onset of symptoms in divers who fly after diving even if they are symptom-free prior to departure. Divers who experience DCS symptoms before departure but nevertheless fly are more likely to have type II DCS, less likely to achieve complete relief after recompression, and more likely to have residual symptoms for at least 3 months.

The recommended postdive preflight surface interval (PFSI) before ascending to higher altitudes (or flying) depends on the diver’s repetitive group designator (residual nitrogen time). The relative risk of developing DCS increases with greater residual nitrogen times and shorter PFSI (Fig. 141-10). For example, the risk of developing DCS is seven times greater for PFSIs of 12 hours after a dive to 130 fsw than for PFSIs of 24 hours after a dive to 60 fsw.

Long PFSIs (up to 48 hours) may be necessary to reduce the risk of DCS after deep, multiday repetitive diving, particularly if the dives required decompression stops (exceeding the no-decompression limits). Some dive computers calculate time-to-flight intervals, which tend to be somewhat shorter than most guidelines based on residual nitrogen timetables.

Flying should be delayed for at least 12 hours after diving if less than 2 hours of total dive time was accumulated in the preceding 48 hours. For multiple-day, unlimited diving, flying should be delayed for at least 24 hours. It is prudent to admit all recompressed patients or to advise them to remain within 60 minutes of the hyperbaric facility for 24 hours. Patients recompressed after DCS or AGE should not fly for 72 hours.

The U.S. Navy’s guidelines recommend that the patient not return to diving for 7 days after recompression for type I DCS and for 4 weeks after type II DCS. The sport diver who experiences DCS type II symptoms or AGE should probably never dive again.

After treatment for pulmonary barotrauma, it is advisable to evaluate the diver with a spiral volumetric chest CT scan to determine whether there are any preexisting pathologic conditions (e.g., bullae) that could put the diver at risk for recurrence before further diving. Chest CT is not recommended in routine medical screening before participating in scuba diving without a history of pulmonary barotrauma.

Figure 141-10. The risk of decompression sickness relative to flying. fsw, feet of seawater; msw, meters of seawater. (From Freiberger JJ, et al. The relative risk of decompression sickness during and after air travel following diving. Aviat Space Environ Med 73:983, 2002.)

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
High-altitude illness represents a spectrum of clinical entities that have hampered the activities of mountaineers, merchants, military forces, aviators, and explorers throughout time. This illness is seen clinically in one of several forms that overlap and share a common pathophysiology. Acute mountain sickness (AMS) is the relatively benign and self-limited presentation, whereas high-altitude pulmonary edema (HAPE) and high-altitude cerebral edema (HACE) represent the potentially life-threatening manifestations of high-altitude illness.

Worldwide, it is estimated that approximately 40 million individuals live above 8000 feet, and 25 million live above 10,000 feet. Rather than these high-altitude residents, the groups at risk for acute altitude illnesses are those who ascend into mountainous regions. Mountain sports activities and tourism are attracting increasing numbers of participants each year. This, combined with the rapid ascent made possible by air transportation, results in more unacclimatized individuals at risk for high-altitude illness. More than 1 million visitors travel annually to the remote high mountain ranges of Asia, Africa, and South America. Approximately 35 million visitors travel annually to high-altitude recreation areas in the western United States.

The incidence of high-altitude illness depends on many variables. The rate of ascent, previous altitude exposure, and individual genetic susceptibility are the most important factors. Sleeping altitude, final altitude reached, and duration of stay at any altitude also play a role. AMS is very common (67% incidence) among mountain climbers on Mt. Rainier who ascend quickly (1 or 2 days) to 14,410 feet. Trekkers who fly into the Khumbu region to explore the Mt. Everest area have a higher incidence of AMS (47%) compared with those who walk (23%). Skiers who visit resorts in the western United States from sea level generally fly or drive to the region but sleep at relatively lower altitudes than the other groups mentioned. Among this population, AMS occurs in approximately 25%. Given the large number (approximately 25 million) of visitors in Colorado each year, this is not a trivial matter. The incidence of HAPE varies from 0.01 to 2% in most studies but has reached 15.5% among soldiers flown directly to 14,500 feet without a chance to acclimatize at a lower altitude. The incidence of HACE is lower, and although it usually occurs with HAPE, it can be seen as an isolated entity. Both HAPE and HACE are more common with a longer duration of visit and higher sleeping altitude.

Age may be a relative risk factor. Most studies on children suggest that they have the same incidence of AMS as adults. One small study of tourists in Chile evaluated children 4 to 48 months old and found higher AMS scores and lower oxygen saturations compared to those of their parents. Younger individuals (<20 years old) are more likely to develop HAPE, although HAPE is extremely rare in children younger than 2 years of age. Gender does not affect the incidence of AMS; however, women may have less risk of developing HAPE. No relationship appears to exist between AMS development and the menstrual cycle.

The number of elders visiting mountain resorts is increasing. Many of these individuals have underlying health problems, including lung disease (10%), heart disease (25%), and hypertension (30%). Despite these conditions, the risk for AMS development in this subset of older adults may be less than that in other age groups. Nevertheless, there are indications that elders may not react well to acute high-altitude exposure. Pulmonary vital capacity decreases almost one third in elders ascending from sea level to 14,000 feet for 1 week, producing a large decrease in both oxygen saturation and maximal oxygen uptake during exercise. For elders residing at moderate elevations, oxygen saturation is approximately 92% at rest.

DEFINITIONS

Moderate altitude is between 8000 and 10,000 feet of elevation. Although most people do not experience significant arterial oxygen desaturation until they reach higher altitudes, high-altitude illness is common with rapid ascent above 8000 feet. Individuals with underlying medical problems may be predisposed to developing altitude illness at lower levels.

High altitude is between 10,000 and 18,000 feet. Most serious altitude illness occurs at these levels. The pathophysiologic effects of high altitude begin when the oxygen saturation of the arterial blood begins to fall below the 90% level. The sigmoidal shape of the oxyhemoglobin dissociation curve prevents a significant fall of arterial oxygen saturation (Sao2) in most individuals until an altitude of approximately 12,000 feet. At this altitude, the steep portion of the curve is encountered, and rapid desaturation begins, with relatively small increases in altitude (Fig. 142-1). Some predisposed individuals may desaturate to less than 90% at altitudes as low as 8000 feet.

Extreme altitude is above 18,000 feet. At this height, complete acclimatization generally is not possible, and long visits above this level result in progressive deterioration.
Chapter 142: Environment and Toxicology

### Environmental Considerations

Barometric pressure decreases logarithmically as the altitude rises. The partial pressure of oxygen (P\textsubscript{O\textsubscript{2}}) in the atmosphere also decreases as altitude rises, but it remains a constant 20.93% of the barometric pressure. The shape of the earth is slightly flattened at the poles and bulging at the equator. The atmospheric envelope that surrounds the earth has a similar shape; therefore, the barometric pressure is lower at higher latitudes than it is at the equator. For example, it has been calculated that it would be impossible for a climber to reach the summit of Mt. Everest without supplemental oxygen if the mountain happened to be in a more northern latitude.

The atmospheric envelope also undergoes a seasonal tide that causes a variation in its local thickness. This results in barometric pressures that are lower and "relative altitudes" that are higher during the winter season. Local weather can also have a significant effect on barometric pressure from day to day. A low-pressure front can reduce the barometric pressure 12 to 40 mm Hg (500–2500 feet) and result in a significant temporary increase in relative altitude.

### Acclimatization

The term "acclimatization" refers to the series of integrated adaptations that take place at high altitudes, which tend to restore the oxygen pressures within the tissues toward normal sea level values despite the lowered P\textsubscript{O\textsubscript{2}} of the atmosphere. These processes occur gradually and involve multiple respiratory, cardiovascular, and hematologic adjustments. Gradual ascents made by mountaineers over several weeks have allowed the successful summiting of many of the world’s highest peaks, including Mt. Everest (29,029 feet), without supplemental oxygen and without the serious manifestations of altitude illness. If rapid exposure to extreme altitudes is attempted, acclimatization is impossible, and the individual loses consciousness and may die in a matter of minutes.

Acclimatization begins at the altitude that causes the oxygen saturation of arterial blood to fall below sea level values. The altitude at which this occurs depends on the rate of ascent, the duration of exposure, and individual physiology. People with preexisting conditions that reduce oxygen saturation or content will have a decreased altitude tolerance. Of particular importance are both acute and chronic cardiac and respiratory illnesses. Most healthy, unacclimatized visitors to high altitude will not desaturate significantly (to less than 90%) until they reach elevations higher than 8000 feet.

The risk of high-altitude illness also depends on an individual’s inherent ability to acclimatize. Some people acclimatize easily without any clinical symptoms developing, whereas others may transiently develop AMS during acclimatization. This variability may involve the genetic mediation of oxygen transport capabilities between individuals. Previous, successful acclimatization may be predictive of future responses in similar conditions.

The most important physiologic change that occurs during acclimatization is an increase in minute ventilation, causing a decrease in the partial pressure of carbon dioxide (P\textsubscript{aCO\textsubscript{2}}). The alveolar gas equation states that as the P\textsubscript{aCO\textsubscript{2}} decreases, a corresponding increase in P\textsubscript{aO\textsubscript{2}} occurs, thereby increasing arterial oxygenation (Box 142-1). Therefore, the level of ventilation determines alveolar oxygen for a given inspired oxygen tension.

When a person arrives at high altitude, the peripheral chemosensors in the carotid bodies respond to a decrease in P\textsubscript{aO\textsubscript{2}} and signal the respiratory control center in the medulla to increase ventilation. This increase in ventilation is known as the hypoxic ventilatory response (HVR), which can be inhibited or stimulated by numerous factors, including ethanol, sleep medications, caffeine, cocoa, prochlorperazine, and progesterone. The magnitude of the HVR varies among individuals and may be genetically predetermined.

As ventilation increases, a respiratory alkalosis occurs that acts as a negative feedback system on the central respiratory center, limiting any further increase in ventilation. Within 24 to 48 hours of ascent, the kidneys excrete bicarbonate in an effort to compensate for the alkalosis. As the pH normalizes, ventilation rises slowly, reaching a maximum after 6 to 8 days. This process is facilitated by acetazolamide. The ability to achieve an adequate HVR varies and is related to the ability to acclimatize; thus, a poor HVR makes an individual more likely to fail acclimatization and develop AMS.

The release of catecholamines on ascent stimulates the circulating system to increase cardiac output. This is manifested by an elevation in heart rate, blood pressure, cardiac output, and venous tone. Except at extreme altitudes, acclimatization results in the resting heart rate gradually returning to near sea level values. Resting relative tachycardia is evidence of poor acclimatization. As the altitude increases, a decrease in maximal heart rate capacity occurs and, at the limits of acclimatization, maximal and resting heart rates converge.

Another component of the acclimatization process is the hematopoietic response to high altitude, consisting of an

---

**Box 142-1: Alveolar Gas Equation**

\[
P_{\text{aO}_2} = P_{\text{iO}_2} (P_{\text{aCO}_2} / R)
\]

- \(P_{\text{aO}_2}\): Partial pressure of oxygen in alveolus
- \(P_{\text{iO}_2}\): Partial pressure of oxygen in inspired air
- \(P_{\text{aCO}_2}\): Partial pressure of oxygen in carbon dioxide in alveolus
- \(R\): Respiratory quotient
A poor HVR resulting in relative hypoventilation may result from either the individual’s genetic predisposition or extrinsic factors, such as medications, that decrease the ventilatory drive. Whenever the HVR is decreased, the protective effects of hyperventilation are lost and the hypoxemia of high-altitude exposure is exacerbated.

The periodic breathing associated with high-altitude exposure may result in periods of apnea during sleep, causing severe arterial oxygen desaturation, which further exacerbates hypoxemia. Significant hypoxemia initiates multiple systemic responses that involve the circulatory, pulmonary, endocrine, and central nervous systems.

Hypoxemia alters fluid homeostasis, resulting in a generalized fluid retention followed by the shift of fluid into the intracellular spaces. This is manifested by peripheral edema, decreased urinary output, and increased body weight in patients with AMS. Several different mechanisms may account for these fluid shifts, including arginine vasopressin (AVP) levels and sympathetic stimulation that may be centrally mediated. AVP levels are elevated in some cases of AMS and HAPE and decreased in others. Aldosterone, plasma renin, and atrial natriuretic levels are higher in people with AMS.

The hypoxemia that results from high-altitude exposure causes pulmonary artery hypertension and elevated capillary pressures that play the cardinal role in the development of HAPE. Exercise and cold stress at altitude may increase hypoxemia and exacerbate pulmonary hypertension. Pulmonary blood volumes and pulmonary hypertension are increased by sympathetic nervous system stimulation and catecholamine release. In HAPE-susceptible individuals, pulmonary hypertension becomes severe and an uneven distribution of pulmonary vasoconstriction results in overperfusion, increased capillary pressures, distention, and leakage in the remaining vessels. This explains the patchy nature of the infiltrate seen on a chest radiograph with HAPE. The mechanism for the uneven vasoconstriction in HAPE may be due to decreased nitric oxide bioavailability at the pulmonary tissue level. Overperfusion of a restricted vascular bed as the pathogenesis of HAPE is supported by the observation that people born with congenital unilateral absence of a pulmonary artery are very susceptible to HAPE. These individuals deliver their entire cardiac output to one lung, predisposing them to overperfusion injury.

The importance of the excessive rise in pulmonary artery pressure in HAPE is emphasized since lowering the pressure during ascent prevents HAPE. This implicates increased vascular pressure rather than inflammation as the primary cause of the vascular leak. The resultant mechanical shear forces lead to endothelial damage and changes in membrane permeability. Inflammatory mediators appear to be a secondary response to the mechanical injury caused by overperfusion. Once the vascular leak occurs and alveolar fluid accumulates, a defect in transepithelial sodium transport impairs the clearance of alveolar fluid and contributes to HAPE development. Alveolar fluid clearance is up-regulated by beta-adrenergic agonists and inhaled beta-agonists that successfully prevent and treat HAPE.

Preexisting inflammation may also be a risk factor for HAPE. A preexisting respiratory infection during ascent to high altitude increases susceptibility to HAPE, particularly in children. Inflammation may “sensitize” the pulmonary endothelium to mechanical injury and increase susceptibility to HAPE during ascent.

The clinical manifestations of AMS/HACE are the result of central nervous system dysfunction. The speculative mechanistic theories involve altered cerebral hemodynamics and
biochemical inflammatory mediators. The vasodilatory response to hypoxemia causes an increase of cerebral blood flow and cerebral blood volume. Hypoxemia can also result in impaired vascular autoregulation that causes increased pressure transmission to the brain's capillary beds, resulting in vasogenic edema. The addition of systemic hypertension with strenuous exercise at high altitude may overwhelm the brain vasculature, resulting in transcapillary leakage. In susceptible individuals, the vasodilation, vasogenic edema, or associated changes in intracranial pressure may result in structural changes that cause pain-sensitive brain regions to be stretched or compressed, causing the sensation of headache in patients with mild AMS.

Additional circumstances, however, may be necessary for the development of vasogenic edema. Biochemical inflammatory mediators may contribute to edema formation. Vascular endothelial growth factor, the inducible form of nitric oxide synthase, reactive cytokines, and free radical formation may mediate brain endothelial permeability. The roles that these play in altitude illness pathophysiology are unclear. Magnetic resonance imaging (MRI) in patients with HACE reveals white matter changes consistent with vasogenic edema (see Fig. 142-6). Vasogenic edema is also implicated in the origin of AMS. This breakdown of the blood-brain barrier is most likely the result of both mechanical factors and biochemical mediation of permeability.

MRI data reveal that cytotoxic edema is also present in severe AMS. Cytotoxic edema results from hypoxic cell damage most often associated with ischemic hypoxic insults. Failure of the adenosine triphosphate-dependent sodium pump allows sodium to accumulate within the cells, increasing intracellular water to maintain the osmotic equilibrium. Cytotoxic intracellular water accumulation may not be the primary mechanism for the development of HACE but, rather, the result of the increased cell ischemia initially caused by vasogenic edema.

Hypobaria appears to play a role in the development of AMS. Sea-level experiments that expose subjects to hypoxia alone do not result in AMS; however, when hypoxia is combined with hypobaria, AMS does occur. Although microbubble formation and fluid retention may be a mechanism, the exact role of hypobaria regarding altitude pathophysiology is unclear.

These responses to hypoxia and altitude exposure occur in both susceptible individuals and those who remain free of AMS. Thus, there must be an overall permissive factor in a subject at risk for AMS that fails to compensate for brain swelling. Ross proposes and Hackett supports the “tight fit” hypothesis to explain AMS development and its inherent individual susceptibility. The adequacy of the space to buffer changes in brain and cerebrospinal fluid (CSF) volume plays a key role in determining which individuals develop symptoms of
altitude illness. As brain volume increases due to increased cerebral blood volume, the volume-buffering capacity of the central nervous system may prevent an immediate rise of intracranial pressure. As brain volume increases, the intracranial CSF is displaced via the foramen magnum into the space available in the spinal canal. Increased absorption of CSF by the arachnoid villi and decreased CSF production also occur. Individuals with less intracranial and intraspinal CSF buffering capacity have less compliance and become more symptomatic (i.e., develop AMS) from mild brain swelling. This tight fit hypothesis is supported by MRI and computed tomography studies.53,70,71

**ACUTE MOUNTAIN SICKNESS**

**Clinical Presentation**

The symptoms of mild AMS are very similar to those of a viral syndrome, an ethanol “hangover,” or simple physical exhaustion. The vague nature of this presentation results in many misdiagnoses. In the setting of recent high-altitude exposure, these symptoms warrant a presumptive diagnosis of AMS until proven otherwise.

To diagnose AMS, a patient must be in the setting of a recent gain in altitude, be at the new altitude for at least several hours, and report a headache plus at least one of the following symptoms: gastrointestinal upset (anorexia, nausea, or vomiting), general weakness or fatigue, dizziness or light-headedness, or difficulty sleeping (Box 142-2).72 The headache may vary from mild to severe, is generally bitemporal and throbbing in nature, and is worse during the night and on awakening or suddenly becoming upright. Anorexia and nausea, with or without vomiting, are common, and the other symptoms described can range in severity from mild to incapacitating. The disturbance of sleep caused by periodic breathing is common in all visitors to high altitudes but is exacerbated in the setting of AMS. The symptoms of AMS develop within a few hours after arrival at high altitude and generally reach maximum severity between 24 and 48 hours, followed by a gradual resolution. Most individuals become symptom free by the third or fourth day. Those who do not resolve their symptoms should descend because they may develop more serious manifestations of altitude illness, especially if they continue to ascend.

Among infants and very young children, AMS is manifested by increased fussiness, decreased playfulness, decreased appetite, and sleep disturbance.8 In most cases of AMS in very young children, all of these symptoms are present. In children, many of the symptoms manifested by AMS can also result from the disruption of normal routine. A change in environment, sleeping accommodation, or eating habits can result in a fussy, unhappy child. In addition, the occurrence of an acute illness can also mimic AMS in young children. If occult bacteremia or another serious illness is suspected in a young child, descent to lower altitude is recommended to eliminate the confounding variable of altitude illness.

There are no diagnostic physical findings in cases of mild AMS. Although dyspnea on exertion is universal at high altitudes, dyspnea at rest is an early indication of HAPE, and a careful examination for pulmonary edema is indicated. Similarly, any evidence of cerebellar dysfunction, such as mild ataxia or alteration in mentation, mandates descent because of early evidence of HACE.

**Management**

The proper management of AMS must include adherence to the principle that after the symptoms of altitude illness occur, further ascent to a higher sleeping altitude is contraindicated. Halting ascent or activity to allow further acclimatization may

**Figure 142-4.** Chest radiograph of a patient with high-altitude pulmonary edema. A, Before treatment. B, After treatment. (Courtesy of Richard Nicholas, MD.)

---

**BOX 142-2 ACUTE MOUNTAIN SICKNESS**

*Incidence:* 12 to 67%, varies with rate of ascent; rare below 8000 feet, most common with rapid ascent to altitudes greater than 10,000 feet

*Symptoms and signs:* Headache, anorexia, nausea, fatigue, dizziness, difficulty sleeping

*Treatment:* Mild cases are usually self-limited and do not require treatment; discontinue ascent, rest; for moderate case, administer acetazolamide, aspirin, or acetaminophen for headache; prochlorperazine for nausea; supplemental oxygen if available; descend if persistent or severe; add dexamethasone in severe cases

*Prevention:* Gradual ascent to allow acclimatization; high-carbohydrate diet, avoidance of ethanol or smoking; acetazolamide if ascent is rapid or known history of recurrent acute mountain sickness
reverse the symptoms; however, continuing the ascent exacerbates the underlying pathologic processes and may lead to disastrous results. The presence of neurologic abnormalities (e.g., ataxia or altered mentation) or evidence of severe pulmonary edema mandates immediate descent because these signs indicate a progression of AMS to the more dangerous forms of altitude illness.

Mild AMS may be treated by stopping further ascent and waiting for acclimatization to occur. This may take 1 to 4 days. AMS that becomes worse or does not respond to maintenance of altitude, rest, and pharmacologic intervention mandates descent. A descent of 1500 to 3000 feet effectively reverses high-altitude illness in most cases. Descent should be continued until improvement is seen, and efforts to minimize exertion should be instituted during the descent.

Supplemental oxygen administration relieves AMS symptoms, including when given in small amounts (1-2 L/min) during sleep. In the wilderness, oxygen tanks are heavy and are usually unavailable in adequate amounts; therefore, oxygen therapy is usually reserved for the more serious manifestations of high-altitude illness. In resort settings, oxygen may be easily available for use in the hotel or condominium. Hyperbaric therapy that simulates descent is also effective.

Treatment of headache, nausea, and insomnia can be beneficial during the course of mild AMS. Aspirin, ibuprofen, and acetaminophen are useful for the treatment of headache; however, narcotic analgesics should be avoided due to depression of the HVR and the respiratory drive during sleep. For nausea and vomiting, prochlorperazine, unlike other antiemetics, stimulates the HVR.

Periodic breathing causes insomnia, which is best treated with the respiratory stimulant acetazolamide. Doses of acetazolamide as low as 62.5 to 125 mg at bedtime may prevent periodic breathing and eradicate insomnia. Benzodiazepines and other sedative-hypnotics should be avoided because of their tendency to decrease ventilation during sleep. Some climbers experience unusual reactions to diazepam at high altitudes, including agitation, hallucinations, and disorientation. These reactions can occur in individuals who have previously used diazepam at lower altitudes without any difficulties. Some studies suggest that low doses of benzodiazepines alone or in combination with acetazolamide are safe at high altitude. Nonbenzodiazepine sleep agents (zolpidem and zaleplon) do not depress ventilation and may prove useful in AMS-related insomnia.

Acetazolamide accelerates acclimatization and, if given early in the development of AMS, rapidly resolves symptoms. A dose of 250 mg of acetazolamide at the onset of symptoms and repeated twice daily is effective therapy for AMS. The treatment of AMS in children has not been formally studied, but anecdotal experience supports the use of acetazolamide in children. The dose for children is 2.5 mg/kg/dose given twice daily to a maximum of 250 mg.

Acetazolamide is a carbonic anhydrase inhibitor that induces a renal bicarbonate diuresis, causing a metabolic acidosis that increases ventilation and arterial oxygenation. This respiratory stimulation improves sleep when the hypoxemia caused by periodic breathing is eradicated by acetazolamide. The diuretic effects attenuate fluid retention common in patients with AMS. This agent also lowers CSF volume and pressure, which may play an additional role in its therapeutic and prophylactic use. Noncarbonic anhydrase inhibitory effects of acetazolamide include chemoreceptor effects on ventilatory drive, alterations of cerebral blood flow, relaxation of smooth muscles, and up-regulation of fluid resorption in the lungs.

The most common adverse reactions to acetazolamide include paresthesias and polyuria. Less common reactions include nausea, drowsiness, tinnitus, and transient myopia. Carbonic anhydrase inhibition at the tongue causes dysgeusia, altering the flavor of carbonated beverages, including beer. Acetazolamide is a non-antibiotic sulfa compound that is usually well tolerated by individuals with an allergy to sulfa antibiotics. Approximately 10% of individuals allergic to sulfa antibiotics will experience an allergic reaction. When feasible, administer a trial dose of acetazolamide in “sulfa allergic” patients prior to ascent. Acetazolamide should be avoided in breast-feeding mothers and pregnant women.

Dexamethasone is an effective alternative treatment for AMS. An initial dose of 8 mg is followed by 4 mg every 6 hours. No significant adverse reactions are reported; however, symptoms can recur when the treatment is withdrawn. Although dexamethasone can resolve the symptoms of AMS, it does not play a role in acclimatization. Concurrent use with acetazolamide is advocated by some to promote acclimatization. The mechanism of action is unclear. It is known to have anti-inflammatory properties, possibly reduce cerebral blood flow, and block the action of vascular endothelial growth factor. Reduction of AMS symptoms while using dexamethasone may be the result of these or its euphoric effects. We believe that dexamethasone should generally be reserved for use in the setting of acetazolamide intolerance or in more advanced cases of AMS, especially to help facilitate descent.

**Prevention**

Most of the symptoms of mild AMS are benign and well tolerated. These symptoms, however, can be unpleasant and debilitating to the point that travel, business, or vacation plans must be interrupted. Up to 50% of individuals with AMS report a decrease in activity.

Slow ascent, allowing adequate time for acclimatization, is the best method of prevention; however, often the time constraints of most vacationers make slow ascent unrealistic. The major concern lies in the sleeping altitude during any individual ascent. Ideally, the first night should not be spent at an altitude higher than 9000 feet, with a subsequent increase of not more than 2000 feet each night. One extra night of acclimatization should be added for every 3000 to 4000 feet of altitude gain above 10,000 feet. If the journey begins at an altitude above 10,000 feet, then three nights should be spent acclimatizing before any further increase in sleeping altitude. Excursions during the day to higher altitudes with a return to a lower sleeping altitude aid in acclimatization.

Mild to moderate exercise is thought to aid in acclimatization; however, overexertion can contribute to the development of AMS. Maintenance of adequate hydration is also recommended. Normal urine output and relatively clear (unconcentrated) urine reflect adequate hydration. Recommendations for hyperhydration are frequently given in the lay literature, yet no evidence supports this advice. Drinking excessive amounts of free water may lead to hyponatremia and possibly complicate altitude illness.

In some cases, such as arrival at a high-altitude airport or the immediate dispatch of rescue personnel to high altitude, a slow ascent is impossible. Mountain climbers commonly ascend at rates that are higher than recommended, and some individuals continue to suffer AMS symptoms despite gradual ascent. Individuals who have a known susceptibility to the development of AMS and those for whom slow ascent is impractical may consider prophylactic pharmacologic intervention.

Numerous studies demonstrate the effectiveness of acetazolamide in preventing AMS in adults. Lower dosages provide similar prophylaxis with fewer adverse reactions than...
higher dosages. The ideal dose is debated. Many studies demonstrate that 250 mg twice daily starting 24 hours before ascent and continuing for the first 2 days at high altitude is effective. To avoid side effects, a lower dose for prevention is suggested. A dose of 125 mg given twice daily was effective in one study but not in another. Although unstudied, the recommended dosage of acetazolamide for AMS prophylaxis for children is 2.5 mg/kg/dose up to 125 mg total given twice daily, and this weight-based approach may reduce side effects in smaller adults.

Dexamethasone also prevents AMS. The lowest effective dosage is 4 mg every 6 hours. Some patients experience the rapid onset of AMS after dexamethasone is discontinued. Dexamethasone does not facilitate acclimatization but, rather, reduces nausea and enhances mood. In most cases, dexamethasone use should be reserved for treatment of AMS rather than prophylaxis. Military or rescue personnel rapidly ascending to high altitude and individuals with acetazolamide intolerance are candidates for prophylaxis with dexamethasone. The combination of acetazolamide and dexamethasone may be more effective than either drug alone.

Because of its antioxidant properties, *Ginkgo biloba* is proposed for preventive therapy of AMS. Although the results of several small studies were encouraging, a well-designed study showed no evidence that gingko is effective.

Oxygen is an effective prophylactic modality for rescue personnel. Adequate supplies must be available to ensure the safety of all team members for the entire duration of the rescue. Air drops of oxygen can be lifesaving when weather or terrain prevents the immediate arrival of rescue personnel.

**HIGH-ALTITUDE PULMONARY EDEMA**

High-altitude pulmonary edema is the most common fatal manifestation of severe high-altitude illness (Box 142-3). Although HAPE is uncommon below 10,000 feet, it can occur, and even be fatal, at altitudes as low as 8000 feet. Episodes occurring between 8000 and 10,000 feet are usually related to heavy exercise, but at higher altitudes pulmonary edema can also occur at rest or with light activity.

Some individuals are susceptible and experience HAPE with each ascent to altitude. Rarely, the congenital absence of a pulmonary artery exaggerates the pulmonary vascular response to hypoxia, resulting in recurrent HAPE at elevations lower than expected. Many patients, however, have a single episode of HAPE and subsequently are able to return to high altitude without a recurrence. Conversely, those with previously uneventful high-altitude exposures may have HAPE develop in a future ascent.

Individuals who have been residents at high-altitude locations for extended periods may have pulmonary edema develop on re-ascent from a trip to low altitude. This phenomenon has been termed reentry HAPE. The incidence of reentry HAPE is not established; however, there seems to be an increased risk for children and young adults and possibly a greater incidence compared with HAPE experienced by low-altitude residents during their initial ascent. This apparent increased susceptibility among children to develop HAPE is probably the result of developmental changes in pulmonary vascular reactivity and tone.

**Clinical Presentation**

The initial symptoms of HAPE usually begin insidiously two to four days after arrival at high altitude. Most cases occur during the second night, but HAPE may develop rapidly, with early symptoms apparent after just a few hours at high altitude. Marked dyspnea on exertion, fatigue with minimal to moderate effort, prolonged recovery time, and dry cough are early manifestations of the disease. The symptoms of AMS usually occur concurrently with the development of HAPE.

As the HAPE patient deteriorates, usually through the night, the dyspnea intensifies with effort and is unrelated by rest. Dyspnea at rest must be recognized as a red flag that warns of the development of a serious pulmonary problem. The cough becomes productive of copious amounts of clear, watery sputum, and in severe cases hemoptysis may be seen. As the condition intensifies, cerebral edema or simply severe hypoxemia causes central nervous system dysfunction, such as ataxia and altered mentation. Coma may follow and precede death in a few hours if oxygen therapy or descent is not instituted.

The physical examination reveals a few rales in patients with mild HAPE, usually found in the region of the right middle lobe, progressing to unilateral or bilateral rales and then to diffuse bilateral rales and also rhonchi and gurgles audible without the stethoscope. Cyanosis of the nail beds alone may progress to severe central cyanosis. Tachypnea and tachycardia become more pronounced as severity increases. Elevated temperatures are common, and a concurrent respiratory tract infection is occasionally seen, especially in children.

**Ancillary Tests**

Chest radiographs can help elucidate the nature of the illness. The infiltrates seen in HAPE victims are alveolar and patchy in distribution, with areas of clearing between the patches. Unilateral infiltrates may be present in mild cases; however, bilateral infiltrates are seen in more advanced cases, with involvement of the right midlung field most common (see Fig. 142-4). Pleural effusion is rare but may be present in severe cases. The extent of the edema present on the chest radiograph roughly parallels the clinical severity. Of note, the
radiographic findings of cardiomegaly, bat-wing distribution of infiltrates, and Kerley B lines, which are typical of cardiogenic pulmonary edema, are absent in cases of HAPE.

Radiographic evidence for HAPE clears rapidly after initiation of treatment; some mild cases may clear in 4 to 6 hours, and most clear by 24 hours. Radiographs of patients with severe HAPE may reveal infiltrates that persist for as long as 2 weeks, even though the clinical symptoms have resolved.

An electrocardiogram reveals tachycardia and evidence of right heart strain, including right axis deviation, P wave abnormalities, tall R waves in the precordial leads, and S waves in the lateral leads. Hemodynamic studies reveal increased pulmonary vascular resistance, elevated pulmonary artery pressures, and normal pulmonary wedge pressures. Echocardiography studies demonstrate high estimated pulmonary artery pressures, pulmonary vascular resistance, and normal left ventricular function.

**Differential Diagnosis**

Pneumonia can be misdiagnosed in the setting of HAPE because the symptoms and signs of pneumonia are similar to those of HAPE. The incidence of pneumonia and the common organisms responsible for pneumonia at high altitude are unknown, but visitors to high altitudes may be predisposed to acquiring bacterial infections because of impaired T lymphocyte function. Patients who present with symptoms compatible with pneumonia at high altitude should be treated for HAPE. If any doubt exists regarding the diagnosis of HAPE versus pneumonia, empiric antibiotic therapy should be initiated. Because of the mild immunosuppression coincident with high-altitude exposure, the treatment of any serious infectious illness at high altitude requires oxygen and descent in addition to local wound care and antibiotics.

High-altitude bronchitis and pharyngitis are common problems among climbers. They may result from the increased ventilation of cold, dry air across the upper airway mucosa, causing mucosal inflammation. Copious sputum production is sometimes seen, and antibiotic therapy usually is not helpful. Coughing spasms may be severe and require codeine. Other therapeutic measures include hydration, lozenges, and steam inhalation.

Death from pulmonary embolism at high altitude is described. Hypercoagulability results from altitude effects and hyperviscosity caused by elevation in hematocrit and blood viscosity. Venous stasis, caused by immobility when confined to a sleeping bag inside a tent, is also a predisposing factor for deep vein thrombosis. The symptoms and signs of pulmonary embolism can mimic those of HAPE; however, embolic disease tends to have a more rapid onset, and pleuritic chest pain is a more prominent feature.

**Management**

In remote settings, where oxygen and medical expertise may be unavailable, immediate descent is a lifesaving measure after diagnosing HAPE. Delaying descent while HAPE progresses or waiting for rescue personnel to initiate evacuation can prove fatal. Descents of 1500 to 3000 feet should be adequate for a rapid recovery. The recovered victim may be able to re-ascent in 2 or 3 days.

Warmth and rest are important in HAPE therapy to avoid cold- or exercise-induced pulmonary hypertension. Mild cases of HAPE can be treated without descent or oxygen with 1 or 2 days of bed rest. Oxygen administration increases the rate of improvement. Moderate cases can be treated without descent if bedrest and adequate supplies of supplemental oxygen are available. Any treatment plan that does not include descent mandates serial examinations by clinicians with experience in managing high-altitude illness.

On difficult terrain or in weather conditions that hamper efforts to descend, oxygen administration (or hyperbaric therapy) is a lifesaving measure. Rescue personnel should air drop oxygen supplies if immediate evacuation to lower altitudes will be delayed. High-flow rates of oxygen (6–8 L/min) by mask should be delivered initially to victims with severe HAPE until improvement is seen. Flow rates can then be lowered until recovery or descent is completed. Delivering oxygen with a continuous positive airway pressure mask is more efficacious than normal oxygen delivery.

Hyperbaric therapy simulates descent without the administration of supplemental oxygen. Several portable, lightweight (approximately 15 pounds), fabric hyperbaric chambers are available and pressurized manually (Fig. 142-5). These chambers generate 103 mm Hg (2 psi) above the ambient pressure. This simulates a descent of 4000 to 5000 feet at moderate altitudes, and at the summit of Mt. Everest it would simulate a descent of approximately 9000 feet. These devices can be lifesaving in patients with HAPE and HACE. Some nonambulatory patients are able to descend under their own power after a few hours in hyperbaric chambers.

In treating HAPE, agents that lower pulmonary artery pressure, pulmonary blood volume, and pulmonary vascular resistance or enhance alveolar fluid clearance are useful but not as effective as oxygen and descent. Furosemide, 80 mg twice daily, is beneficial, and when combined with morphine for the initial dose, it results in even greater diuresis and clinical improvement. Some authors caution that deleterious dehydration may result from furosemide therapy and that the potential ventilatory depression caused by morphine can further increase the severity of the underlying hypoxemia of AMS. Others argue that during the state of antidiuresis found with severe AMS, no documented deleterious effects from this treatment exist.

Although furosemide may be useful, the advent of pulmonary vasodilators has displaced the use of furosemide for HAPE. Nifedipine, a pulmonary vasodilator, is especially useful when oxygen is unavailable or descent is impossible. Nifedipine does not improve pulmonary hemodynamics as much as oxygen or descent, and it does not have an additive effect when administered with oxygen. Treatment with 10 mg of nifedipine every 4 to 6 hours or 10 mg followed by 30 mg of a slow-release preparation administered once or twice daily is effective. A response to treatment with improvement
in symptoms is usually noted within 15 to 30 minutes after the first sublingual dose. Patients should be monitored for the development of hypotension during nifedipine administration.

Phosphodiesterase-5 inhibitors are less likely to produce hypotension, and although known to be useful for HFAE prevention, they have yet to be studied for HAPE therapy. Alveolar fluid clearance is upregulated by beta-adrenergic agonists, and inhaled beta-agonists have been used successfully for both prevention and therapy of HAPE.48,49

**Disposition**

Mild to moderate cases of HAPE can be treated with oxygen, rest, and careful monitoring. Resort doctors at moderate altitudes observe HAPE patients on oxygen therapy to ensure adequate oxygenation. These patients are then discharged to their hotel with supplemental oxygen and monitored for improvement or deterioration. In severe HAPE or milder cases that do not improve with therapy, descent is warranted. Rapid recovery is usually seen after descent to lower altitudes, and observation of the patient in the emergency department to ensure adequate room air oxygenation is generally adequate. Occasionally, admission to the hospital is indicated to maintain the SaO2 greater than 90%. Hypocapnia, alkalosis, and radiographic evidence of HAPE may persist for several days. After oxygen saturation remains greater than 90% on room air and clinical improvement is apparent, the patient can be discharged. If the patient requires air travel to return home (cabin pressures equal approximately 8000 feet), additional recovery time before travel or arrangement for supplemental oxygen administration is advised. Detection of a heart murmur in a patient with HAPE should lead to an evaluation searching for cardiac structural anomalies that may increase pulmonary vascular resistance. An evaluation for underlying congenital heart disease is warranted after an episode of HAPE in a young child.

**Prevention**

As with all forms of serious altitude illness, a gradual ascent that allows time to acclimatize and immediate cessation of further ascent at the onset of symptoms are the most effective means of prevention. Individuals with a prior history of HAPE should also avoid extreme exertion during the first 2 days at altitude. With a prior history of HAPE, prophylactic therapy should be considered. Clinical experience suggests that acetazolamide prevents HAPE, and animal studies demonstrate its utility in reduction of hypoxic pulmonary vasoconstriction. The nonspecific pulmonary vasodilator nifedipine, 20 mg (slow release) three times daily before ascent and continued at altitude for 3 days, is effective in preventing a recurrence of HAPE. Phosphodiesterase-5 inhibitors are selective pulmonary vasodilators that increase cyclic guanosine monophosphate availability. Sildenafil (40 mg every 8 hours) and tadalafil (10 mg every 12 hours) are both effective in preventing HAPE. The phosphodiesterase-5 inhibitors have the added benefit that they are less likely to induce systemic hypotension than calcium channel blockers. Dexamethasone (8 mg every 12 hours) started 2 days prior to ascent also prevents HAPE. The mechanism for dexamethasone prevention is also due to pulmonary artery pressure reduction.44

**HIGH-ALTITUDE CEREBRAL EDEMA**

High-altitude cerebral edema is the least common but most severe form of high-altitude illness. Death from HACE at as low as 8200 feet is reported, although most cases occur above 12,000 feet. Mild AMS can progress to severe HACE with coma in as few as 12 hours. Although the usual time course is 1 to 3 days for the development of severe symptoms, it may occur in 5 to 9 days (Box 142-4).112

**Clinical Presentation**

High-altitude cerebral edema is characterized by evidence of global cerebral dysfunction. The symptoms of severe AMS (headache, fatigue, and vomiting), as well as those of HAPE (cough and dyspnea), are usually present. HACE-specific signs include ataxia, generalized seizures, slurred speech, rarely focal neurologic deficits, and altered mentation. The latter can range from mild emotional lability or confusion to hallucinations and decreased levels of consciousness that may proceed to coma and death. MRI of patients with HACE reveals white matter changes consistent with vasogenic edema (Fig. 142-6).64

Altered consciousness and cerebellar ataxia are the most sensitive signs for early recognition of HACE. The early appearance of ataxia reflects the particular sensitivity of the cerebellum to hypoxia. Ataxia alone is an indication for immediate descent. Retinal hemorrhages are common but often occur as an isolated finding. Papilledema and, occasionally, cranial nerve palsy also occur in the setting of increased intra-
cranial pressure. Differentiating between HACE and stroke may be difficult. Although rare, the occurrence of cerebral thrombosis and transient ischemic attacks, in the absence of high-altitude illness, is documented at high altitude.\textsuperscript{114,115} The absence of any other evidence for high-altitude illness, or signs that persist despite adequate treatment of high-altitude illness, suggests the presence of a vascular lesion.

**Management**

Early recognition and initiation of descent are the keys to successful therapy for HACE. High-flow oxygen should be administered, if available. Steroid therapy is recommended and may result in recovery from HACE without neurologic deficits. The initial dose of dexamethasone is 8 mg parenterally, or orally in mild cases, followed by 4 mg every 6 hours.

Patients with severely altered levels of consciousness require tracheal intubation and hyperventilation to control elevated intracranial pressures. Diuretics (e.g., furosemide) and hypertonic solutions (e.g., mannitol) decrease intracranial pressure.

Hyperbaric treatment of HACE is also effective and may result in temporary improvement and allow self-rescue. Conversely, coma may persist for several days after descent to lower altitudes, so placement of HACE patients in a hyperbaric device may only delay the more comprehensive care available in the hospital setting.

Long-term neurologic deficits, such as ataxia and cognitive impairment, are reported after recovery from acute episodes of HACE. Both transient and long-lasting neurobehavioral impairments can occur in mountaineers after climbing to extreme altitude without experiencing clinical HACE.\textsuperscript{118} Some of these sequelae can persist for 1 year. Because of the potential for long-lasting neurologic injury, the clinician who treats high-altitude illness must be extremely sensitive to the early manifestations of HACE. Early treatment for HACE generally results in good outcomes, but after coma is present, the mortality rate exceeds 60%.\textsuperscript{117}

**HIGH-ALTITUDE RETINAL HEMORRHAGE**

High-altitude retinal hemorrhage (HARH) is the most common type of retinopathy in visitors to high altitude.\textsuperscript{119} These hemorrhages are common at altitudes over 17,500 feet, although they can occur at lower levels.\textsuperscript{119}

The exact incidence of HARH is unknown because most patients are asymptomatic, with HARH noted only on retinoscopy. HARH is not generally related to the presence of mild AMS but does seem to be related to strenuous exercise at high altitude. At any altitude, in the setting of severe HAPE or HACE, retinal hemorrhages are commonly noted.\textsuperscript{119}

Hemorrhages are generally seen in the peripapillary area and throughout the fundus but usually spare the macula (Fig. 142-7). Retinal hemorrhages are self-limited and resolve without treatment in 2 or 3 weeks. With macular involvement, central scotomata may be noticed for several years, gradually resolving. In some cases, however, these visual defects are permanent. HARH is more likely to occur among individuals with a previous history of these hemorrhages. Usually, this does not pose a contraindication to return to high altitude unless the macular region is involved.

**ALITUDE AND UNDERLYING MEDICAL CONDITIONS**

In individuals with diseases such as moderate to severe chronic obstructive pulmonary disease (COPD) and coronary artery disease, these illnesses are often aggravated by the relatively hypoxic atmosphere at higher elevations. They may have a more difficult time acclimating, which predisposes to the development of high-altitude illness. Table 142-1 describes the risk associated with travel to altitude in individuals with a variety of underlying comorbidities.

**Respiratory Illnesses**

Travelers with COPD to moderate altitudes have underlying anatomic and physiologic changes that predispose them to develop hypoxemia, sleep apnea, pulmonary hypertension, and ventilation disorders. COPD is a risk factor for the development of AMS.\textsuperscript{3} Although oxygen saturation remains more than 90% in a healthy, awake individual until an altitude of 8000 feet, patients with COPD may desaturate below 90% at lower altitudes. Attempts to predict the need for oxygen use at altitude based on hypoxic breathing at sea level have resulted in the development of nomograms to predict arterial oxygen partial pressure at the expected high-altitude exposure (see Table 142-1). These have not been clinically useful. Travel to 5000 feet did not result in significant desaturation below 90% in one group of COPD patients and did not produce significant adverse effects on the systemic circulation in another group at 8000 feet.\textsuperscript{120} High altitude increases hypoxic...
pulmonary vasoconstriction and may potentiate the development of cor pulmonale, which is known to adversely affect survival at sea level.\(^\text{122}\) Colorado, for example, has a relatively low incidence of COPD but a higher mortality rate than expected from emphysema.\(^\text{122}\) Individuals with chronic COPD should be advised of the potential need for oxygen supplementation when traveling to moderate altitude, especially if they are already using oxygen at sea level or if dyspnea or fatigue becomes worse. Use of a pulse oximeter that is readily available can guide the need for increased oxygen use.

Patients with asthma, on the other hand, may have fewer problems at altitude due to decreased allergens, pollutants, and decreased airflow turbulence. There have been no descriptions of asthma exacerbations at altitude, although at elevation oxygen saturations might be lower. Even those with exercise-induced bronchospasm do not have worsening symptoms while exercising at 5000 feet.\(^\text{123}\) In addition, AMS incidence is not increased in asthmatic people.\(^\text{123}\) People with asthma traveling to higher elevations should continue their usual medications and carry a rescue supply of bronchodilators and steroids.

Patients who ascend to high altitude with preexisting primary or secondary pulmonary hypertension should be considered HAPE susceptible, and those with primary pulmonary hypertension should be considered at increased risk for HAPE.\(^\text{124}\) Patients with known pulmonary hypertension should be advised against travel to higher elevations. If travel cannot be avoided, then supplemental oxygen should be used. Phosphodiesterase-5 inhibitors and steroids may also be effective.\(^\text{44}\)

### Cardiovascular

Individuals with a history of congestive heart failure, angina, dysrhythmias, or coronary bypass surgery are rarely studied in this setting. In theory, people with a diseased myocardium should be advised to avoid trips to high altitude due to decreased environmental oxygen availability. However, no studies have reported increased mortality in visitors to these locations. To the contrary, long-term residents at high altitude may be protected from coronary artery disease due to increased collateral vessel formation or a decrease in the development of atherosclerosis.\(^\text{125–127}\)

Several authors have safely exposed elderly people with known or suspected coronary artery disease to acute hypoxia at altitude, while breathing low oxygen mixtures, or when being placed in a hypobaric chamber.\(^\text{126}\) In contrast, Levine and colleagues’ investigation of elderly people with known coronary disease did demonstrate some risk.\(^\text{129}\)

Patients with heart disease have increased sympathetic activity during the first 3 days at altitude, as do all travelers. The resultant increase in heart rate and blood pressure increases cardiac work and myocardial oxygen consumption and might increase dysrhythmias. Although both cardiac rhythm abnormalities and ST segment and T wave electrocardiogram changes are reported, none of these changes are associated with any clinical evidence of myocardial ischemia.\(^\text{128,130}\) Limited data suggest no increased risk for sudden cardiac death or myocardial infarction at altitudes up to 8000 feet.

The small increase in heart rate and blood pressure that occurs when first visiting altitude might be expected to exacerbate angina in patients with known disease. Even when individuals with stable angina are exercised, there is conflicting evidence regarding the probability of inducing malignant dysrhythmias or untoward cardiac events.\(^\text{129,131}\) In a study of 22 patients with recent percutaneous coronary intervention or coronary artery bypass graft with a submaximal exercise routine at 11,400 feet, there was no evidence of myocardial ischemia or significant arrhythmias despite an elevated oxygen demand, heart rate, and lactate level.\(^\text{132}\) Travelers with heart disease who ascend to moderate altitudes do not appear to have an increased incidence of AMS.\(^\text{5,13}\)

Recommendations for travelers with mild stable coronary artery disease should include gradual ascent, limitation of activity especially in the first few days at elevation, and continuation of antianginal and antihypertensive medications. Individuals who have more severe, symptomatic coronary disease or those in a high-risk group (low ejection fraction, abnormal stress test results, and high-grade ventricular ectopy) should avoid travel to high altitudes. Ascent to moderate elevations can be suggested on an individual basis with the previously mentioned precautions. Individuals with heart failure who travel to altitude may require increased use of diuretics to promote diuresis and promote acclimatization. Although not tested, acetazolamide prophylaxis may be useful for speeding acclimatization and preventing AMS and its accompanying fluid retention.\(^\text{102}\) If the anticipated workload at altitude is greater than the individual is accustomed to at sea level, exercise stress testing at this increased workload before ascent should be considered.\(^\text{133}\)

Hypertension

High-altitude travel produces a mild increase in blood pressure and heart rate in healthy individuals because of increased catecholamine activity and resultant sympathetic tone. This increase begins in the first few days after ascent, is maximal at 2 or 3 weeks, and returns to baseline values over time due to a down-regulation of adrenergic receptors if one stays at high altitude or on descent to sea level.\(^{134,135}\) The incidence of hypertension in sea-level dwellers traveling to high altitude is 10 to 25%.\(^{136}\) Although there is no difference in blood pressure readings in either normotensive or hypertensive individuals when measured at low altitudes (3000 feet), significant increases occur in both blood pressure and heart rate at altitudes greater than 9800 feet.\(^{137}\) This suggests that people with severe hypertension should travel only to moderate altitudes. For individuals who develop mild hypertension while traveling at altitude, treatment is not routinely necessary because the hypertension will rarely become dangerously high and will improve on descent. Although individual variability exists, patients with hypertension should be monitored frequently in the first few days at altitude and anti-hypertensive medications continued. For hypertensive patients with a rapid rise in blood pressure and who will be staying for several weeks, an alpha-blocker, nifedipine, or an ACE inhibitor should be considered.\(^{138}\)

Sickle Cell Disease

Patients with sickle cell disease are affected by the hypoxemia occurring at low to moderate altitudes (5000–6500 feet). Up to 20% of patients with hemoglobin sickle cell and sickle cell-thalassemia disease may experience a vaso-occlusive crises, even under pressurized aircraft conditions.\(^{139}\) Oxygen is therefore advised for air travelers who have sickle cell disease. Although most people with sickle cell trait remain asymptomatic, this subgroup can experience the development of left upper quadrant pain as a result of splenic ischemia or infarction. Non-blacks, usually of Mediterranean origin, who have sickle cell trait may be more prone to the development of splenic infarctions than are blacks.\(^{140,141}\)

Pregnancy

Studies of permanent high-altitude residents in Colorado and Peru show an increased incidence of complications in maternal, fetal, and neonatal life.\(^{1}\) Infants born at high altitude have a lower birth weight compared to infants born at sea level. Fetal growth retardation at high altitude is believed to be the result of a reduction in uterine artery blood flow.

Pregnancy-induced hypertension, proteinuria, and peripheral edema (manifestations of toxemia and preeclampsia) are more common at high altitudes and may also be related to maternal hypoxemia.\(^{142}\) Although hypertension in pregnancy is more common at high altitudes, no evidence exists for an increase in spontaneous abortions, abruptio placentae, or placenta previa.

Travel by pregnant women to moderate altitudes appears to be safe, but caution is advised for lowland women with normal pregnancies who wish to travel above 13,000 feet, for pregnant women who wish to remain at high altitude for a prolonged period, and for women with complicated pregnancies.

Radial Keratotomy

Although currently less popular, radial keratotomy may cause individuals to experience visual changes with ascent to altitude. This results from corneal swelling from ambient hypoxia because the cornea obtains its oxygen almost entirely by diffusion from the atmosphere. In normal corneas, this swelling is uniform. After radial keratotomy, the swelling is exacerbated and nonuniform secondary to the incisions.\(^{143}\) Photorefractive keratotomy, which uses a laser technique that does not produce incisions but instead shaved the cornea, does not result in similar problems. Patients with radial keratotomy may require glasses of increasing refraction if they ascend to altitudes above 9000 feet.\(^{144}\)

KEY CONCEPTS

- The symptoms of AMS can resemble a viral syndrome and include headache, nausea, anorexia, fatigue, and insomnia.
- The management of altitude illness must include adherence to the principle that after the symptoms occur and until symptoms resolve, further ascent is contraindicated.
- Dyspnea at rest is an early symptom of HAPE. As the HAPE patient’s condition deteriorates, the dyspnea intensifies with effort and is unrelieved by rest.
- Cerebellar ataxia must be recognized as an early symptom of HACE, and descent is mandatory.
- Effective prophylaxis options for altitude illness include acetazolamide for AMS and nifedipine or tadalafil for HAPE. Dexamethasone should be reserved for acetazolamide intolerance or to facilitate descent with severe AMS.

CHAPTER 143  Drowning

David B. Richards and Andrew L. Knaut

PERSPECTIVE

Unintentional drowning accounted for 3308 deaths in the United States in 2004.1 Worldwide, it is estimated that 500,000 people die after drowning annually, which exceeds mortality due to war.2 Drowning is the fourth most common cause of accidental death in the United States. Among children 1 to 4 and 10 to 14 years old, drowning is second only to motor vehicle crashes as the leading cause of injury mortality.1,3,4 Toddlers and older teenagers are at greatest risk of death by drowning, with annual incidences of 2.45 and 1.47 per 100,000, respectively.1 Boys account for almost 80% of victims older than 1 year. Race plays a decided, although incompletely understood, role: Black males between ages 15 and 19 years have the highest annual incidence of drowning mortality (4.25 per 100,000), and black children between ages 5 and 14 years drown at more than three times the rate of white children of the same age.1,5,6

The incidence of drowning with nonfatal outcomes is less well known. The Centers for Disease Control and Prevention estimates that for every child who dies by drowning in the United States, five receive emergency department care for a submersion event, and half of these children require hospitalization.6 Among all age groups, it is estimated that one to four hospitalizations secondary to nonfatal submersion occurs for every drowning death.7,9

Submersion injuries occur in domestic settings such as swimming pools, hot tubs, bathtubs, and large buckets and in all forms of natural bodies of water. A review of all drowning deaths among individuals younger than 20 years in the United States during a 1-year period reveals that 55% of infants younger than 1 year who drown did so in bathtubs, and nearly 16% drowned in large household buckets.7 Most (56%) children 1 to 4 years old drowned in artificial pools, whereas most (63%) deaths among older children occur in natural bodies of freshwater.7 Drowning in the United States follows clear temporal patterns: Two thirds of pediatric deaths occur between the months of May and August, and most submersion injuries occur on weekends between the hours of noon and 8:00 pm.7 Submersion victims older than 20 years are most often participating in water sports or using watercraft.

PRINCIPLES OF DISEASE

Definitions

Traditionally, the terminology used to describe submersion injuries has been confusing and impractical. In the past, drowning referred to death within 24 hours of suffocation from submersion in a liquid, whereas near-drowning described victims who survived at least 24 hours past the initial event regardless of the outcome. In 2005, the World Health Organization (WHO) published a new policy defining drowning in an attempt to clarify documentation and better track submersion injuries worldwide. Drowning was defined as “the process of experiencing respiratory impairment from submersion/immersion in liquid.” Furthermore, the WHO policy states that “drowning outcomes should be classified as: death, morbidity, and no morbidity. … Use of the terms wet, dry, active, passive, silent, and secondary drowning should no longer be used.”2 As such, the term near-drowning should not be used, and the association of the term drowning with a fatal outcome should be abandoned.

Immersion syndrome refers specifically to syncope resulting from cardiac dysrhythmias on sudden contact with water that is at least 5°C less than body temperature. Proposed as mechanisms for the syndrome are vagal stimulation leading to asystole and ventricular fibrillation secondary to Q-T prolongation with a massive release of catecholamines on contact with cold water. The resultant loss of consciousness leads to secondary drowning. The risk of immersion syndrome is proportional to the difference between body and water temperature. Wetting the face and head before entering the water may prevent the inciting sequence of events.3

Risk Factors

Ethanol consumption in proximity with water is a major risk factor for submersion injury or death. Acute ethanol intoxication may be a contributing factor in 30 to 50% of drownings among adults and adolescents.4,7 In one study of boating fatalities, most of which were due to drowning, an association between blood ethanol concentration and risk of death from drowning while using watercraft was established. Odds ratios of fatality from drowning followed a trend from 2.8 (95% confidence interval [CI] 1.6, 4.8) for a blood ethanol concentration (BEC) of 1 to 49 mg/dL to 37.4 (95% CI 16.8, 83.0) for a BEC of 150 mg/dL or greater compared with sober case controls.30

The relationship between swimming ability and the risk of drowning is unclear. No direct evidence exists to suggest that inexperienced swimmers are more likely to drown. On the contrary, skilled swimmers have greater exposure to water and may be more prone to submersion incidents.31 Numerous medical conditions confer an increased likelihood of drowning or submersion injury. Seizure disorders
Pathophysiology

Unexpected submersion triggers breath-holding, panic, and a struggle to surface. Air hunger and hypoxia develop, and the victim begins to swallow water. As breath-holding is overcome, involuntary gasps result in aspiration. The quantity of fluid aspirated, rather than the composition, determines subsequent pulmonary derangement. The historical emphasis on pathophysiologic differences between freshwater and salt water aspiration with respect to resultant electrolyte imbalance, hemolysis, and fluid compartment shifting was based on animal studies conducted in the early 20th century.

Subsequent investigations have revealed that significant intravascular abnormalities do not occur until the amount of aspirated water exceeds 11 mL/kg of body weight, and autopsy studies show that most drowning victims aspirate less than 4 mL/kg.17 In one review of the hospital treatment of 91 submersion victims, no patient required emergent intervention for a significant electrolyte abnormality.19 Aspiration of 1 to 3 mL/kg of either freshwater or salt water destroys the integrity of pulmonary surfactant, leading to alveolar collapse, atelectasis, noncardiogenic pulmonary edema, intrapulmonary shunting, and ventilation-perfusion mismatch.3 Profound hypoxia and metabolic and respiratory acidosis ensue, leading to cardiovascular collapse, neuronal injury, and, ultimately, death.

The classic hypothesis was that 10 to 15% of drowning victims die without aspirating a significant amount of water. Death from such “dry” drowning putatively results from severe laryngospasm causing hypoxia, convulsion, and death without fluid entering the lungs. An exhaustive review of the literature failed to corroborate this hypothesis.19 Dry drownings more appropriately reflect deaths from causes other than simple submersion.

Many factors may influence the pathophysiologic sequence of events in submersion injury and affect the chance of survival, including age, water temperature, duration and degree of hypothermia, the diving reflex, and the effectiveness of resuscitative efforts. Because of a lower ratio of body mass to surface area, children develop hypothermia more quickly and to a greater degree after immersion in cold water than adults. Hypothermia lowers cerebral metabolic rate and is neuroprotective to some extent for victims of submersion injury.20 Despite dramatic case reports of patients surviving prolonged submersion in cold water with full neurologic recovery, hypothermia is generally a poor prognostic finding. Cold water immersion speeds the development of exhaustion, altered consciousness, and cardiac dysrhythmia. The diving reflex may also play a protective role in infant and child submersion. Activation of the diving reflex by fear or immersion of the face in cold water shunts blood centrally to the heart and brain. Apnea and bradycardia ensue, prolonging the duration of submersion tolerated without central nervous system damage.21

CLINICAL FEATURES

Symptoms and Signs

Many submersion injuries are witnessed. Toddler drownings are an important exception, however, often occurring because of a lapse in supervision. Occasionally, the history of coughing, choking, or vomiting in a patient found near a body of water suggests the diagnosis. Signs of pulmonary injury may be obvious in a submersion victim who is hypoxic, cyanotic, and in obvious respiratory distress or arrest. More subtle clues, such as increased respiratory rate and audible rhonchi, rales, or wheezes, should alert the clinician to evolving respiratory compromise. Submersion victims swallow a significantly greater volume of water than is aspirated, and gastric distention from positive-pressure ventilation during rescue is common. As a result, 60% of patients vomit after a submersion event.3 Aspiration of gastric contents greatly compounds the degree of pulmonary injury and increases the likelihood that acute respiratory distress syndrome will ensue. In addition, aspiration of particulate contaminants such as mud, sewage, and bacteria may obstruct the smaller bronchi and bronchioles and greatly increase the risk of infection both bacterial and fungal in nature.22

Victims with central nervous system injury may present with symptoms ranging from mild lethargy to coma with fixed and dilated pupils. Adverse neurologic findings on initial presentation do not preclude full neurologic recovery, although in general patients whose duration of submersion or resuscitation exceeds 25 minutes have an unfavorable outcome.23 Central nervous system injury results from the initial hypoxic or ischemic insult and from the cascade of reperfusion injury that follows reestablishment of cerebral blood flow after an arrest. The release of inflammatory mediators and the generation of oxygen free radicals in the postresuscitative period contribute to cytotoxic cerebral edema, compromise of the blood-brain barrier, and increased intracranial pressure. Cerebral arteriolar vasospasm and enhanced platelet aggregation impede cerebral perfusion at the macrocirculatory and microcirculatory levels.24

Cardiac dysrhythmias may incite a submersion injury or develop as its consequence. Hypoxemia, acidosis, and, potentially, hypothermia are the primary factors responsible for dysrhythmias ranging from ventricular tachycardia and fibrillation to bradycardia-asystole. Electrolyte disturbances are rarely significant enough to be dysrhythmogenic.18

Other clinical sequelae of submersion injury may include acute renal impairment, present in approximately 50% of patients as the result of lactic acidosis; prolonged hypoperfusion; and, in some instances, rhabdomyolysis.25 Coagulopathy as a consequence of associated hypothermia or disseminated intravascular coagulation may also occur.

Prognostic Factors

Many factors may help predict patients who will survive a submersion injury neurologically intact. Submersion victims who arrive in the emergency department alert with normal hemodynamics are unlikely to experience neurologic impairment. Circumstantial variables that portend a poor outcome include victim age younger than 3 years, submersion for longer than 5 minutes, and initiation of cardiopulmonary resuscitation (CPR) more than 10 minutes after rescue.25 With the exception of victim age, however, such measurements are generally either unknown or inaccurately estimated at the time of a patient’s arrival in the emergency department. Objective findings on emergency department arrival that are associated with...
an unfavorable prognosis include hypothermia, severe acidosis, unreactive pupils, a Glasgow Coma Scale score of 3, and asystole or the need for ongoing CPR. Neurologically intact survival is reported for individual patients even with several of these factors present, and none of several proposed scoring systems using combinations of these variables shows 100% predictive power.25,27,30,31

**DIFFERENTIAL CONSIDERATIONS**

The precipitants of a submersion injury, such as drug or ethanol intoxication, cardiac arrest, hypoglycemia, seizure, and attempted suicide or homicide, should be considered in a patient who is found unresponsive in the water. For pediatric victims, child abuse or neglect must also be considered as a potential etiology.

Potential head or cervical spine injury is an important consideration when a history of trauma is associated with the submersion. A review of 2244 cases of submersion injury in King, Pierce, and Snohomish counties in Washington state, however, identified only 11 (0.5%) patients with a cervical spine injury. Each patient had either clinical signs of serious trauma or a history of motor vehicle crash, fall from height, or diving into the water.32 Unless such factors are present, routine cervical spine immobilization for submersion victims is not warranted.

**DIAGNOSTIC STUDIES**

Cardiac monitoring and an electrocardiogram must be obtained to determine the presence of significant dysrhythmias or Q-T prolongation. Pulse oximetry, capnography, and arterial blood gases should be monitored closely in all submersion victims for signs of hypoxemia, hypercarbia, and acidosis. Blood glucose, serum creatinine, and electrolytes should be obtained, although serum creatinine and electrolytes are usually normal on initial presentation. Similarly, complete blood count is often normal with the exception of leukocytosis. Toxicologic screening may be appropriate depending on the circumstances of the submersion. Subsequently, evidence of renal failure, hepatic dysfunction, and disseminated intravascular coagulation may be noted on laboratory testing.

The initial chest radiograph may underestimate the severity of pulmonary injury, although infiltrates or pulmonary edema may be evident within hours. Cranial computed tomography is rarely contributory initially unless significant trauma or other pertinent pathology is suspected. Magnetic resonance imaging of the brain may predict neurologic outcome after submersion injury, but its prognostic value is not optimal until 3 or 4 days elapse.31,33

**MANAGEMENT**

Salient details of the events surrounding the accident should be ascertained rapidly. Resuscitation of pulseless and apneic patients should be attempted initially in most cases because bystander estimates of total submersion time are often inaccurate. The clinical presentation of severe hypothermia often mimics death, and case reports exist of functional recovery for individuals submerged for 66 minutes.34,35

For a victim without vital signs, outcome depends on the interval preceding CPR. Mouth-to-mouth assisted ventilation should begin immediately, even before the victim is extricated from the water. Chest compressions are impractical before extrication but should be initiated as soon as the individual is placed on a solid surface. Maneuvers such as those proposed by Heimlich and Patrick to remove fluid from the lungs are ineffective and dangerous in a victim at risk for asphyxiation and may delay ventilation. Use of such maneuvers is not recommended unless there is reason to suspect airway occlusion by a foreign body.36

On arrival in the emergency department, cardiac monitoring and continuous pulse oximetry should be established. A core temperature obtained with a low-reading probe is indicated for any unstable or lethargic patient. Rewarming a hypothermic patient may suffice for hemodynamic stabilization and improvement in mental status. Bedside blood glucose measurement and empirical naloxone administration are warranted. In a spontaneously breathing patient, monitoring for signs of developing pulmonary injury should be established. Initial chest radiographs are often unremarkable even in the setting of serious and evolving pathology. Frequent arterial blood gas determinations are essential in submersion victims.

The decision regarding tracheal intubation should be based on clinical impression and objective determination of the adequacy of oxygenation and ventilation. Apparent or developing respiratory distress, the absence of protective airway reflexes, and significant associated head or chest injuries are indications. A PaCO$_2$ greater than 50 mm Hg mandates intubation and mechanical ventilation. Patients unable to maintain an oxygen saturation greater than 90% or a PaO$_2$ greater than 60 mm Hg on high-flow oxygen require positive airway pressure to increase functional residual capacity, decrease intrapulmonary shunting, and reduce ventilation-perfusion mismatch. In an awake patient, this may be accomplished by face or nasal mask (continuous positive airway pressure), but the risk of potential gastric distention, vomiting, and aspiration must be considered. Otherwise, tracheal intubation and mechanical ventilation with positive end-expiratory pressure is necessary. The hemodynamic consequences of positive end-expiratory pressure must be monitored carefully because increased intrathoracic pressure may compromise venous return and cardiac output. Decreased cranial venous return may impede cerebral perfusion.

No consensus exists with regard to the appropriate length of resuscitative effort for hypothermic submersion victims in the emergency department. The safest parameter is to continue until the core temperature reaches at least 30°C to 35°C because cerebral death cannot be diagnosed accurately in hypothermic patients with temperatures below this level. This parameter may not always be practical, however, because brain-dead patients are often poikilothermic.

The administration of corticosteroids in the setting of submersion injury and potential acute respiratory distress syndrome does not improve outcome. Similar to maternal use, the administration of corticosteroids in the setting of submersion injury and potential acute respiratory distress syndrome does not improve outcome. Similarly, empirical antibiotics do not increase survival and should be administered only to the rare patient who was submerged in grossly contaminated water or who shows signs of infection or sepsis.

Interventions such as induced or permissive hypothermia aimed at attenuating reperfusion injury after anoxic brain insult are the focus of intense investigative effort, but no consensus exists regarding their use in submersion injury. A case report of twin toddlers with identical submersion injury and subsequent prolonged cardiac arrest indicates that therapeutic hypothermia may be a factor in influencing a good neurologic outcome. One twin was treated with therapeutic hypothermia for 72 hours and had a return to normal neurologic status. The other twin was not cooled and survived, but with significant neurologic impairment. Reports such as this and studies in the resuscitation literature indicate an emerging role for therapeutic hypothermia in some drowning victims. Corticosteroid administration, barbiturate-induced coma, aggressive diuresis, neuromuscular blockade, and hyperventilation do not improve
neurologic outcome and, particularly in the case of hyperventilation, may be harmful.21

**DISPOSITION**

Symptomatic patients must be admitted for treatment. Patients with a history of apnea, unconsciousness, or hypoxia and any patients who manifest dysrhythmia or an abnormal chest radiograph also require admission. Patients who are asymptomatic on presentation to the emergency department, maintain a normal room air oxygen saturation, and have no chest radiograph or arterial blood gas abnormalities can be discharged safely after an observation period of 6 hours.31,38 Careful instructions regarding symptoms or signs of delayed pulmonary complications are necessary, and the patient should be discharged in the care of a competent relative or friend.

**Preventive Efforts**

The mortality rate from drowning has decreased steadily since the 1990s in the United States.1,4,31 A similar downward trend in submersion injuries is reported in Great Britain.39 Although the exact causes of this decline are unknown, an increased public awareness of preventive measures and an emphasis on public education with regard to CPR and the dangers of ethanol use in conjunction with water-related activities have contributed significantly to the reduction in fatalities. A longitudinal study of drownings during a 21-year period in King County, Washington, notes that the incidence of death attributable to ethanol use has decreased by 81%.3

Parental education regarding the danger of pediatric drowning is an important focus of preventive effort. Inadequate supervision of children playing in or near water is one of the most common causes of pediatric submersion death, underscoring the importance of increasing awareness of the need for constant oversight of children in this setting.3,40 Most pediatric submersion injuries in swimming pools occur at the victim’s home.9 In most cases, the child was last seen in the house, was left unattended for a moment, and entered the pool on an unfenced side closest to the home with no audible splash or screaming.5 Adequate and fully circumferential fencing of residential pools is a current recommendation of the American Academy of Pediatrics. A meta-analysis of the literature regarding the efficacy of this preventive step reports an odds ratio of 0.27 for drowning or submersion in a properly fenced compared with a nonfenced pool.40,41 Unfortunately, legislation requiring appropriate fencing is poorly adhered to, with only 40% of households compliant in one study.42

Pool covers are inadequate and potentially dangerous as barriers. Solar blankets do not support the weight of a child and can enmesh and obscure a struggling victim from view. A rigid pool cover may convey a false sense of stability to a child tempted to walk across its surface and is considered an insufficient substitute for effective four-sided fencing.40

Medical care providers are a vital resource for enhancing public awareness of the importance of these measures. The literature supports the concept that education in the emergency department with regard to drowning prevention can have a positive impact on patient and family awareness of steps to lessen the likelihood of catastrophic drowning or submersion injury.43,44

**KEY CONCEPTS**

- The fluid medium in which a submersion injury occurs (freshwater versus salt water) is usually of little clinical relevance; all significant submersions induce pulmonary injury and hypoxia based on the amount of water aspirated and the duration of submersion, not the water content.
- Aggressive pulmonary support is essential to optimizing the victim’s chances for a favorable outcome.
- In submersion incidents, the Heimlich maneuver is reserved for patients with a suspected airway occlusion by a foreign body.
- No prognostic scale or clinical presentation accurately predicts long-term neurologic outcome; normal neurologic recovery is documented in patients with prolonged submersions, persistent coma, cardiovascular instability, and fixed and dilated pupils.
- Hyperventilation, steroids, dehydration, barbiturate coma, and neuromuscular blockade do not seem to improve outcome.

CHAPTER 144  Radiation Injuries

Christopher B. Colwell and Vincent Markovchick

HISTORICAL PERSPECTIVE
AND EPIDEMIOLOGY

The technology of the 20th and 21st centuries has ushered in the nuclear age. Nuclear energy has significant peaceful industrial and medical uses, but it poses great potential danger as well. Although the safety record involving the use of radiation and radioisotopes is excellent overall, the hazards involved are well known as a result of the near-disaster that occurred at Three Mile Island in Pennsylvania in 1979, the disastrous accident at the Chernobyl Nuclear Power Station in the former Soviet Union in 1989, and the potential for disaster that occurred at a uranium processing plant in Tokaimura, Japan, in 1999.1,2 The potential contamination of large numbers of people has and will continue to stress the capabilities of existing emergency medical systems.

The only wartime use of atomic and nuclear energy was the detonation of atomic bombs over Hiroshima and Nagasaki in 1945. Many nations now have nuclear weapons in their arsenals, however, and the possibility of terrorist groups obtaining and using such weapons does exist. Because the spent fuel from a nuclear power reactor can be reprocessed into plutonium, which can be used to produce nuclear weapons, more countries have now acquired the necessary raw materials to produce these weapons. The technology is available for the production and use of small, low-yield, tactical nuclear weapons and for megaton-yield, strategic nuclear weapons.

Although the proliferation of nuclear weapon technology and materials along with the growth of global terrorism raise new concerns about the possibility of a nuclear weapon being used by a rogue nation or terrorist group, a more likely scenario is the production and detonation of a “dirty bomb.” In contrast to a nuclear weapon, which would be difficult to produce, a dirty bomb can be produced and detonated with relative ease. Perhaps the greatest threat from such a bomb lies in its potential to cause widespread terror from fear of radioactive contamination. Although the number of deaths and injuries resulting from a dirty bomb should not exceed those of a conventional explosion, the panic over radioactivity and evacuation measures and the prolonged cleanup efforts that would ensue could wreak havoc for months or years.

A dirty bomb can be produced from existing strontium-90 or cobalt-60 radioactive materials, such as radium and cesium-137 isotopes that are used in cancer therapy and found in many hospitals or university laboratories. Such a weapon can be produced by combining radioactive materials in solid or powder form with a conventional explosive that on detonation would send radioactive material into the area of the explosion and downwind. Although minimal to no harm would be likely from these sources of radiation, there would be tremendous psychological effects.3,4

It is technically much more difficult to produce a nuclear weapon than it is to manufacture a chemical or a biologic weapon. Use of a nuclear weapon by terrorists is highly unlikely unless they obtained such a weapon from existing stockpiles, which would include sources that may have been lost from governmental control in developing countries and areas of the former Soviet Union.

Injury from a nuclear explosion initially involves the mechanical effects of the blast wave that result in large-scale conventional types of blunt and penetrating trauma. Thermal or burn effects are the next threat, followed by the effects of ionizing radiation injury that occurs in proportion to the blast and thermal effects. In addition, radioactive fallout results from a nuclear weapon detonation on or above the ground. Detonation of a nuclear weapon could produce unimaginable devastation and injury from its immediate and long-term effects (Table 144-1).5

Accidents involving peacetime nuclear energy include exposure to and contamination by radioactive sources. The sources of this exposure are medical, industrial, and laboratory accidents that expose people to unacceptably high doses of radiation. Increased transport of such materials has resulted in an increased risk of accidents during transport. Emergency physicians are concerned primarily with the acute effects of exposure and contamination. The long-term effects continue to be studied in the large numbers of the populace exposed to radiation as a result of the Chernobyl accident.6

Nuclear Reactor Incidents

A nuclear weapon, as distinguished from a nuclear reactor, is designed to be autocatalytic (i.e., rather than being self-sustaining, the power grows without bounds after the chain reaction is initiated). The water-cooled nuclear reactors in U.S. power plants are designed to operate in their most reactive configuration. Any material or geometric change (except for removal of the control rods) renders them subcritical. In the graphite-moderated, steam-cooled reactors operating in the former Soviet Union, a nuclear excursion or accident can occur due to loss of coolant. This is what happened at Chernobyl.5

Every nuclear reactor should be housed within a containment structure to prevent the release of radioactivity in the
event of an accident. The Three Mile Island reactor has five layers of defense. It is for this reason that the accident in 1979 resulted in very little radiation being released into the environment. At Chernobyl, however, the containment structure failed, and all the radioactive material from the core of the reactor escaped into the environment. Although the amount of radioactive material released at Chernobyl was only approximately three times that released at Three Mile Island, failure of containment resulted in a 5000 times greater dose of radiation to all within a 10-mile radius of Chernobyl (40,000 mrem compared with 8 mrem from Three Mile Island). Adding to the tragedy, the large amount of radioactive material released into the atmosphere at Chernobyl was carried aloft by prevailing winds, causing increased radiation exposure at long distances.

As a result of human error at a uranium processing plant in Tokaimura, Japan, 49 people were exposed to radiation, 2 of whom received a potentially lethal dose. Enriched uranium was mixed with nitric acid in an open vessel, resulting in Cherenkov radiation. This radiation is released when the speed of a charged particle in a transport medium is so high that it exceeds the velocity of light in that medium. A visible flash results from radiation emitted when the uranium reaches a critical mass and sets off an uncontrolled chain reaction for 20 hours.

Finally, a terrorist attack on a nuclear reactor could result in an atmospheric plume of radioactive iodine and noble gases released through a breach in the reactor core. These gases could have immediate health effects nearby, and long-term effects from radioactive iodine could occur at great distances from the reactor.

### Radon Exposure

Radon gas is a major source of radiation exposure to the general public. Radon and its breakdown products are in the decay chain of uranium-238. Because uranium-238 has a long half-life and is distributed throughout the earth’s rocks and soil, its decay products are ubiquitous. The decay scheme of radon results in the production of four heavy metal isotopes with short half-lives termed radon daughters (Fig. 144-1). These isotopes include alpha-emitting solids that can be inhaled and deposited in the tracheobronchial tree.

Radon-222 is a colorless, odorless, natural radioactive gas that moves by diffusion and pressure flow into basements and lower levels of buildings, where concentrations may reach hazardous levels. Radon daughters can be collected on filters, and alpha activity can be measured. The major source of radon gas is soil containing high levels of radon, such as uranium tailings used for landfill beneath buildings. Radon gas entry can be decreased by sealing basement cracks, and its removal can be enhanced by proper ventilation systems.

Because radon and radon daughters result from the decay of uranium-238, uranium miners sustain some of the highest levels of occupational exposure. These individuals have an increased incidence of lung cancer and interstitial pulmonary fibrosis secondary to radon progeny exposure from inhalation of alpha particles. It is estimated that radon exposure accounts for up to 33,000 lung cancer deaths in the United States each year, making radon the second-leading cause of lung cancer after cigarette smoking. Each year, 15,000 lung cancer deaths in the United States may result from indoor radon exposure; radon in homes may be a significant public health problem.

### PATHOPHYSIOLOGY OF RADIATION EXPOSURE

The electromagnetic spectrum (Fig. 144-2) encompasses a range from microwaves to gamma rays and includes long-wavelength, low-frequency, low-energy forms of nonionizing radiation and progresses to short-wavelength, high-frequency, high-energy forms of ionizing radiation. The frequency and length of these waves determine the energy, measured in units called photons. Frequency is the number of times per second the crest of a wave passes a given point, whereas wavelength is the distance between crests.
Ionizing versus Nonionizing Radiation

Radiation is the transfer of energy in the form of waves, rays, or particles. The term radioactivity refers to the loss of particles (e.g., alpha, beta, or neutrons) or energy (e.g., x-rays and gamma rays) from an unstable atom that is spontaneously decaying. The spontaneous transformation of an unstable isotope to a stable one is referred to as decay, and it may involve the release of ionizing radiation. To understand the effects of radiation exposure on humans requires a distinction between ionizing and nonionizing radiation. Nonionizing radiation refers to all forms of the electromagnetic spectrum, with the exception of x-rays and gamma rays. Nonionizing (in contrast to ionizing) radiation has a long wavelength, low frequency, and low energy. Examples of nonionizing radiation include visible light, radar, radio and television broadcasting, garage door openers, microwave ovens, relay stations, medical diathermy, and satellite communications.

The primary adverse effects of nonionizing radiation are related to local heat production because the energy of nonionizing radiation is essentially all expended in heat. This effect depends directly on the intensity of the source, the distance from the source to the person exposed, and the duration of exposure. Long-term exposure to microwave irradiation at some distance from the source has received extensive study. The most thoroughly researched example involves U.S. State Department employees exposed to long-term microwave irradiation in the U.S. chancery in Moscow. This building was subjected to a direct beam that resulted in exposed rooms having a higher power density than that usually found on the ground near transmission towers. After extensive study, it was concluded that no adverse health effects occurred from this exposure. This and other studies performed on various groups of workers exposed to radiofrequency radiation conclude that the present exposure levels (including microwaves) do not cause significant adverse health effects to the general public; specifically, there is no evidence of either decreased longevity or an increased incidence of cancer. The possibility of hazardous health effects resulting from low-level microwave exposure is an area of ongoing study.

A microwave oven generates 2450-MHz microwaves. This megahertz wavelength can produce hyperthermia above a 25-mW level with a penetration of several centimeters. If a microwave oven has a door leak, a person can be exposed to the thermal effect of microwaves only by placing a body part in direct contact with the area. Electromagnetic waves dissipate at a rate directly related to the square of the distance from the source. In other words, exposure is cut to one fourth at twice the distance from the source. No thermal effect exists at a distance of several feet, but a potential exists for deleterious effects on electronic devices that are sensitive to the wavelength of this electromagnetic radiation.

Ionizing radiation has a short wavelength, high frequency, and high energy. The photons of ionizing radiation carry 1 billion times more energy than the photons of nonionizing radiation. Ionizing radiation induces injury by damaging DNA and other cellular components that can lead to cellular dysfunction or death. It is emitted in the form of alpha and beta particles, gamma rays, and x-rays.

Irradiation versus Contamination and Incorporation

Irradiation

A radioactive substance is one that emits ionizing radiation. It is referred to as a radionucleotide or radioisotope. If such radiation passes through a nearby object, the object is said to have been irradiated. With the exception of the situation in which there is direct exposure to neutrons, the object that has only been irradiated does not become radioactive. When a person has only been irradiated but not contaminated, such as the post-radiation therapy patient, no hazard exists to medical personnel, and the patient may be handled as any other emergency patient.

Contamination

Radioactive contamination is essentially radioactive particulate matter (alpha and beta particles) covering an exposed surface. Contamination is not an acute threat to the life of the patient or the provider, and its presence should not preclude instituting lifesaving measures for associated trauma. This radioactive particulate matter may emit radiation with an effect that is directly related to the time of exposure, distance from the source, and type of contamination. The four types of radiation that exist with the potential to contaminate are alpha, beta, gamma, and neutron radiation, and each presents different hazards (Fig. 144-3).

Alpha radiation consists of particles that are highly charged and composed of two protons and two neutrons. Alpha particles dissipate their energy quickly and travel only a few centimeters in the air. They cannot even penetrate paper and are therefore easily shielded. Even when directly contacting skin, penetration is limited to the thickness of the epidermis. Alpha radiation therefore presents a significant biohazard only when internalized. Alpha particles are produced by alpha emission from many of the heavy radioactive elements, such as pluto-
Gamma rays are electromagnetic waves with no mass and no charge that travel quickly and penetrate tissue deeply, with a fraction of the rays interacting with every layer of tissue. Gamma rays are the most penetrating type of ionizing radiation and travel several meters in air and many centimeters into tissue. Gamma rays are emitted from radioisotopes after beta decay and are the primary cause of the acute radiation syndrome.

Neutrons are unique. When they are stopped, or “captured,” after emission, they commonly cause a previously stable atom to become radioactive. This is the source of radioactive fallout. A surface burst of a thermonuclear weapon instantly vaporizes tons of surface soil, transforming it into highly radioactive material by the intense neutron bombardment. This cloud rises with the fireball and is carried away by the prevailing winds at high altitudes. Its radioactive particles ultimately descend as fallout.

Some gamma exposure also occurs with neutron exposure. In peacetime, significant neutron exposure is likely to occur only around nuclear reactors and accelerators. Quantization of the radioactive material induced by neutron irradiation is helpful in estimating neutron exposures and, sometimes indirectly, the dose of gamma radiation. The induced radioactivity is primarily sodium-24, which can be detected by a whole-

nium and uranium decay. Some Geiger-Mueller counters are not able to detect alpha particles, but are generally excellent for detecting beta and gamma radiation. Due to alpha particles' low penetrating ability, a proportional alpha counter with a special window must be used.

Beta particles have a smaller mass and charge than alpha particles and tend to have a greater velocity. They have a tissue penetration of approximately 8 mm and can cause significant burns to the skin surface, although these burns are not generally visible immediately after the exposure. Since clothing effectively shields covered areas, the primary danger is to exposed skin. Standard skin-cleansing procedures remove most of this contamination. The only means of detection is a radiation-sensing instrument (Geiger-Mueller counter), which all hospitals should have. If exposure to beta particles is allowed to continue, significant exposure to gamma radiation can occur because most radioisotopes decay by beta radiation followed by gamma emission.

Gamma rays are electromagnetic waves with no mass and no charge that travel quickly and penetrate tissue deeply, with a fraction of the rays interacting with every layer of tissue.
body counter or in blood samples. If neutron exposure is suspected, all feces and urine should be refrigerated and saved. All clothing, especially items containing metal parts, such as belt buckles, should also be saved for analysis of neutron-induced radioisotopes.

**Incorporation**

Incorporation occurs when a radioactive material is ingested, inhaled, or absorbed through an open wound.

### TYPES OF EXPOSURE

- **External radiation** exposure results from partial-body or whole-body irradiation from an outside source. The patient may have received a lethal dose but presents no radioactive hazard to other people or the environment. Examples include accidental irradiation of personnel working with fissionable materials in laboratories or with nuclear reactors in nuclear power plants.

- **Incorporation and internal contamination** generally result from inhalation or ingestion of radioactive substances but can also occur from absorption of radioactive substances through open wounds. When this occurs, even alpha particles, which normally present no real health hazard with external exposure, can have long-term effects, including the development of lung cancer. The treatment of this type of exposure is often similar to that of acute poisoning with heavy metals.

- **Wound contamination** involves exposure of an open wound to radioactive material that results in some degree of internal contamination.

Combinations of these types of radiation exposures can occur. The traumatic blast effects of a thermonuclear explosion could result in exposure to all types of radioactivity in addition to causing radioactively contaminated wounds.

### CLINICAL FEATURES AND DIAGNOSTIC STRATEGIES

**Symptoms and Signs**

Radiation injury is caused by deposition of energy in tissue. This energy can lead to damage of cellular structures such as DNA from free radical formation. Cellular repair mechanisms will be less effective with more rapid delivery of higher doses of radiation. **Acute radiation syndrome** (ARS) is a symptom complex that occurs after whole-body irradiation. It varies in nature and severity depending on dose, dose rate, dose distribution, and individual susceptibility. This syndrome can result from external or internal exposure to radiation over a short period of time. The patterns of symptoms and signs of ARS overlap and contain many variables (Fig. 144-4).

The principal units used for expressing the dose of radiation absorbed in living tissue are the **gray** (Gy) (1 Gy = 1 joule of radiation absorbed per kilogram of tissue) and the **radiation absorbed dose** (rad) (1 rad = 100 erg per gram of tissue = 0.01 Gy). The **roentgen equivalent man** (rem) is the dosage of ionizing radiation equal to 1 rad of x-radiation (1 rad = 1 rem). A chest radiograph equals 45 mrem, and flying 3000 miles in a jet at 35,000 feet results in 4 mrem of exposure.

The relative sensitivity of organ systems exposed to the radiation determines the clinical symptoms. Since it is often difficult or impossible to accurately quantitate the absorbed dose of radiation, the symptoms and signs determine the diagnosis, therapy, and prognosis. The presence and timing of nausea and vomiting is an excellent screening tool to detect those who require more urgent medical investigation. When

PART IV  ■  Environment and Toxicology  /  Section One  ■  Environment

Invariably, all organ systems are involved in whole-body irradiation, even though the CNS has a low cellular turnover rate. If the individual is exposed to a nonuniform dose, the radiation dose must be estimated from its biologic effects. The earliest indicator of a significant radiation exposure is the decrease in the absolute lymphocyte count, which can occur within 48 hours after exposure (Table 144-2).5

The LD₅₀ or median lethal whole-body dose (the dose that is lethal for 50% of test subjects), assuming proper medical care, is estimated to be approximately 4.5 Gy. Whole-body exposure of 10 Gy is the maximal survivable dose even with the best medical therapy.5 Doses greater than 20 Gy commonly produce CNS symptoms. These symptoms occur immediately after exposure and include headache, mental status aberration, prostration, vertigo, tinnitus, and sensory and motor changes. If the individual is exposed to a nonuniform dose and the gastrointestinal and hematopoietic systems are spared, there is a chance of survival after resolution of the CNS symptoms. If more than 20 Gy of whole-body exposure occurs, however, fulminating gastrointestinal and CNS symptoms ensue, sometimes within 30 minutes. This indicates a supralethal dose of radiation, and for triage purposes, the death of these patients should be classified as “impending” or “expectant.” If medical resources are scarce, sedation and analgesia should be the only therapies. With whole-body exposure of more than 10 Gy, mortality approaches 100%. If the patient survives the CNS and gastrointestinal system insults, hematopoietic complications are lethal.

The gastrointestinal syndrome occurs regularly at doses higher than 1 Gy. In general, the higher the absorbed dosage, the sooner the onset of symptoms. In its mildest form, nausea and vomiting are short-lived. More protracted nausea and vomiting are seen with higher exposures. The onset of high fever and persistent bloody diarrhea are ominous signs. Death from hematopoietic system failure may result despite aggressive fluid and electrolyte therapy.

A latent period lasting 2 days to 4 weeks from the time of exposure often occurs before the signs of hematopoietic system involvement develop. The earliest sign is often pancytopenia resulting from marrow suppression. This hematopoietic syndrome includes leukopenia and thrombocytopenia with fever, increased susceptibility to infection, petechiae, and hemorrhagic diatheses. The absolute lymphocyte count 48 hours after exposure is a good predictor of hematopoietic system involvement (see Fig. 144-4). If the absolute lymphocyte count is greater than 1200/µL, it is unlikely that the patient has received a clinically significant dose of radiation. If the absolute lymphocyte count falls between 100/µL and 500/µL at 48 hours, a significant or even lethal dose of radiation should be suspected. A level in this range is an indication for protective isolation. Levels less than 500/µL suggest procedures such as the use of hematopoietic growth factors.5,14 If a patient is symptomatic, serial complete blood counts should be performed. Hemorrhagic complications should be treated with platelet concentrates and whole blood or fresh frozen plasma when necessary. Anemia resulting from erythropoietic suppression is not generally of clinical significance.

Erythema from skin burns may be delayed in onset. When secondary to penetrating radiation, they indicate high exposure. Severe skin burns may be a result of nonpenetrating radiation, such as beta particle contamination without accompanying systemic symptoms. These burns can be prevented or tempered by early decontamination. When present, they should be treated as any thermal or chemical burn.

Skin changes that occur can help quantify radiation exposure. Epilation occurs after exposure to 3 Gy, erythema is seen after exposure to 10 Gy, wet desquamation occurs after 20 Gy, and necrosis occurs after 30 Gy of localized skin exposure.5 These responses are similar to those of severe chemical burns.

A key historical point when evaluating a suspicious burn is whether the patient had contact with a hot object or caustic chemical. If the patient does not give a history that clearly explains the burn, particularly if there is a history of carrying a bright metal object that may have been a radioisotope source, the possibility of a radiation burn should be considered.

### MANAGEMENT

#### Out-of-Hospital Care

The history obtained from field personnel is crucial. The exact type of exposure (external versus internal, whole body versus partial body) should be ascertained. If internal exposure is suspected, the portal of entry (inhalation, ingestion, or absorption) and the radioactive material involved should be investigated.
Reducing Exposure

The protection of providers involves reducing exposure to levels that are as low as reasonably achievable. The three classic and effective methods for reducing radiation exposure can be summarized as time, distance, and shielding. The absorbed dose is directly proportional to time. In addition, radiation exposure follows the inverse square law, and it decreases to one fourth at twice the distance from the source. Effective shielding varies from a sheet of paper for alpha particles to less than an inch of aluminum for beta particles and several inches of lead for gamma rays.

Decontamination

If the patient’s condition permits, decontamination should usually be initiated at the scene because many communities lack emergency departments designed for this procedure. In an industrial or laboratory accident, each facility should have a specific protocol and equipment available to initiate the decontamination process. All out-of-hospital personnel should be trained in the decontamination process. Universal precautions, including rubber gloves, shoe covers, and respirators if airborne contamination is suspected, are very effective in protecting personnel and the work area from contamination. The only variation from normal universal precautions is a recommendation to wear two sets of gloves and to change the outer pair when appropriate to avoid cross-contamination.15

The patient’s clothing should be removed and placed in plastic bags. If possible, soap and water cleansing of exposed skin should be performed. All materials, including wash water, should be placed in containers and labeled as radioactive waste. Performing these tasks at the scene minimizes contamination of the ambulance and the emergency department.

If the patient is unstable, rapid and partial decontamination procedures, such as clothing removal, should be initiated at the scene before expeditious transportation to an emergency department. Radio contact with the receiving hospital should be provided to the emergency department to facilitate preparations. If the community disaster plan has a designated hospital for radiation-contaminated victims, they should be transported directly to that facility. Physicians wishing to establish a comprehensive plan to manage radiation accident victims are referred to the National Council on Radiation Protection.16

Emergency Department

Every emergency department designated as a decontamination facility should have a radiation accident protocol. An excellent prototype is that published by Leonard and Ricks.17 This protocol should be included in the policies and procedures manual and posted in the decontamination facility.

Preparation

The chaos that ensued in the wake of the Three Mile Island experience suggests that a community disaster plan should be developed with a predetermined individual empowered to make decisions regarding evacuation and other issues concerning the at-risk population. Upon notification of the numbers and types of patients involved in a radiation exposure accident, a decision should be made regarding implementation of a full disaster plan versus a limited response. The radiation control officer, usually a radiologist or pathologist, should be contacted immediately. The radiation control officer should monitor all patients and medical personnel with a radiation counter and should supervise the “cleanup” and the routing of patients to minimize “tracking,” or spread, of contamination. The role of informational services is critical. Timely and accurate information and instructions should be given to a public relations person for dissemination to the news media to minimize the chaos and paranoia that inevitably result from such incidents.

Decontamination

Contaminated patients should be decontaminated in the field. If they arrive at the emergency department contaminated, they must enter through a separate, protected entrance or be isolated until a decontamination tent can be erected. Since the risk to emergency department staff from radioactive contamination is minimal with universal precautions, medical stabilization and treatment of the patient supersede decontamination efforts in a radiologic emergency.

There is a significant distinction between patients contaminated with radioactive material and those who arrive contaminated with chemical or biologic agents, where decontamination may need to take precedence. All medical personnel should wear protective, disposable clothing, including surgical gloves and shoe covers. Respirators are not required at the hospital but should be used by first responders who are entering a highly contaminated area.3 The emergency suite should contain all equipment necessary for a major resuscitation. If decontamination occurs inside the emergency department, it must have a contained drainage and ventilation system to prevent the spread of waterborne or airborne radioactive contamination. In some hospitals, the only area equipped with such facilities is the autopsy room or morgue.

The radiation disaster plan may necessitate taking resuscitation equipment to this area and providing decontamination and initial care there if this cannot be done in a decontamination facility outside of the emergency department. As opposed to chemical and biologic hazards, radioactive contamination is relatively easy to detect with commonly available survey meters, such as a Geiger-Mueller (GM) instrument, often referred to as a Geiger counter. This should be available in any emergency department that may receive patients exposed to radioactive contamination. Although historically survey meters have not been able to detect alpha radiation, many of the newer devices can detect even small amounts of radioactive contamination and will typically be capable of distinguishing alpha, beta, and gamma radiation.

The patient should be undressed immediately, and all clothing should be placed in sealed containers labeled “radioactive waste.” Removal of clothing can reduce contamination on the patient by 90%.19 Exposed skin should be cleansed with soap and water. Overly aggressive skin washing should be avoided since abraded skin openings could allow increased absorption of radioactive material. Hair should be shampooed. All wastewater, washcloths, and towels should be saved in properly labeled containers. The cleansing process should be repeated as frequently as necessary until the area measures less than twice the background reading on the GM survey meter or until there is no significant reduction in the level of contamination between washes.19 Long hair may need to be trimmed. The nails should be trimmed and meticulously scraped to remove contamination.

Wound Management and Treatment

If the patient has open wounds, the surrounding skin should be decontaminated by scrubbing with soap and water. Adhe-
sive, disposable surgical drapes should be applied, and the wounds should be prepared and irrigated with copious amounts of saline. Frequent monitoring for radioactive contamination determines when irrigation can be discontinued. Surgical débridement should be performed according to the usual indications of dirt and nonviable tissue or continued high readings of radioactive contaminants. The normal principles of wound closure should be followed for contaminated wounds. The wounds in patients who have received whole-body radiation greater than 1 Gy should be closed primarily to prevent infection.5

Since there is minimal risk to providers using universal precautions, emergency surgery or other necessary procedures should not be delayed due to contaminated skin or wounds. Surgical interventions should be performed within 48 hours of the injury when possible in patients who have suffered high-level radiation exposure and trauma. Acute radiation syndrome may be complicated by fluid and electrolyte disturbances. After 48 hours, surgical interventions may need to be delayed until hematopoietic recovery occurs.15

Triage Classification, Further Treatment, and Disposition

Triage is facilitated by presenting symptoms into three categories: survival probable, survival possible, and survival improbable. The survival probable group consists of patients having either no initial symptoms or mild symptoms that subside within a few hours. Radiation exposure in this group is usually less than 2 Gy (200 rem or rads). The initial laboratory studies and serial complete blood counts reveal no depression of the leukocyte count.

The survival possible group includes patients in whom nausea and vomiting are relatively brief (lasting 24–48 hours), followed by an asymptomatic period. After the initial symptoms, these patients exhibit the typical hematologic changes of thrombocytopenia, granulocytopenia, and lymphopenia. The severity of these changes depends on individual susceptibility and the level of the initial radiation dose. These patients should be admitted for fluid and electrolyte therapy if vomiting is severe. Antiemetics may be ineffective. Also, protective isolation precautions are indicated, particularly if there is significant granulocytopenia at 48 hours.

The exposure dosage range for patients in the survival possible group is estimated to be 2 to 10 Gy, with the LD$_{10}$ approximately 3 to 5 Gy. The LD$_{50}$ varies depending on the vigor of supportive therapy. In mass casualty situations, the LD$_{50}$ is in the range of 3.5 to 4.5 Gy. The concept of calculating the LD$_{10}$ versus LD$_{50}$ for human radiation exposure helps determine what level of therapeutic intervention is indicated. A patient who has received an LD$_{50}$ exposure may survive only if hematopoietic growth factors are used, whereas a patient with an LD$_{10}$ exposure may need only low-risk supportive care, such as reverse isolation and intravenous fluids.

The therapy for the survival possible group is based on the exact hematologic derangements. Platelet concentrates are recommended if the count falls below 25 $\times$ 10$^3$/$\mu$L. Appropriate broad-spectrum antibiotics should be considered only if clinical signs of infection appear. Prophylactic antibiotics may be indicated if serious gastrointestinal symptoms, such as vomiting and diarrhea, are present. Prophylactic antifungal agents, such as amphotericin B, may also be indicated. Acyclovir may be useful for oral herpes simplex infection. Colony-stimulating factors (cytokines) that induce bone marrow hematopoietic cells to proliferate may have substantial benefit, with little risk in victims predicted to have moderate or severe bone marrow failure.

Filgrastim and sargramostim, both used in treating patients with neutropenia resulting from myelosuppressive chemotherapy, are useful in radiation accident victims and may hasten recovery of neutrophil counts. Cytokine therapy (filgrastim (G-CSF) 5 $\mu$g/kg per day or sargramostim (GM-CSF)
250 µg/m² subcutaneously) is recommended in healthy individuals with no other injuries who receive exposures estimated to be in excess of 3 Gy and in patients with multiple injuries or burns who receive exposures in excess of 2 Gy. Intravenous hyperalimentation may be necessary for the successful treatment of the gastrointestinal syndrome.

The third group is the survival improbable group. The exposed dose range in this group is estimated to be greater than 10 Gy whole-body exposure. These patients experience rapid onset of fulminating nausea, vomiting, and diarrhea. Intense fluid and electrolyte and hyperalimentation therapy may initially stabilize these patients. They later experience bone marrow aplasia and pancytopenia that is generally fatal. If CNS symptoms appear early, the patient has received a very large dose of radiation. In mass casualty situations, these patients should be triaged into the “impending” or “expectant” death category and provided comfort care.

Consultative Resources

For questions about radiation exposure and injuries, the U.S. Department of Energy can be contacted 24 hours a day at the Radiation Emergency Assistance Center/Training Site (REAC/TS) in Oak Ridge, Tennessee (telephone, 865-576-1005; interactive website, http://www.orau.gov/reacts). For information about the training of physicians, REAC/TS can be contacted at 865-576-3131. The Medical Management of Radiological Casualties Handbook is available online at http://www.afiri.usuhs.mil. The Chemical/Biological Hotline of the National Response Center is 800-424-8802.
CHAPTER 145 General Approach to the Poisoned Patient

Ken Kulig and Louis J. Ling

**PERSPECTIVE**

Most poisoned patients seen in the emergency department are adults with acute oral drug overdoses. Other common clinical scenarios include accidental poisoning in children; drug abuse through smoking, snorting, or intravenous routes; chronic poisoning, usually from environmental, industrial, and agricultural chemical exposure; medication reactions or interactions; and envenomation. Management requires both a general approach and specific actions directed at the particular toxin or toxins involved, as outlined in the various chapters in this section. Clinical studies have modified the management of poisoned patients, such as the use of gastric decontamination, but much of the toxicology literature, especially with unusual poisonings, remains case based. Regional poison centers and medical toxicologists have a concentrated experience in managing poisoned patients and can be called upon for advice and assistance, when necessary.

**INITIAL APPROACH TO THE POISONED PATIENT**

With rare exception, the priorities of care for a poisoned patient are identical to those for all patients coming to the emergency department. Patients who are contaminated with an agent that might injure health care personnel require decontamination before treatment to avoid disabling the hospital staff or the entire health care facility. Except for specific lifesaving antidotes against certain toxins, most poisoned patients require only supportive therapy for recovery. The initial workup should determine whether a specific patient has been exposed to an agent for which an antidote (or other specific treatment) exists.

A thorough poisoning history and toxicologic physical examination are followed by the selective use of laboratory tests. After initial stabilization of a critically ill patient, specific antidote therapy is administered while a detailed history and physical examination are performed. Hypoglycemia must always be considered in a patient with altered mental status or seizures and should be evaluated by bedside glucose testing rather than empiric administration of hypertonic glucose solution. Naloxone can be given to patients with respiratory depression while preparations are made to secure the airway because a possible response may obviate the need for intubation. Flumazenil is not indicated in an undifferentiated overdose patient, and its use should be limited to confirmed acute benzodiazepine overdose in a patient known to not be a regular benzodiazepine user (e.g., an adolescent who impulsively ingests a parent’s benzodiazepine). Indiscriminate use may force a chronic benzodiazepine user into severe benzodiazepine withdrawal. Likewise, the patient may have ingested tricyclic antidepressants or other drugs likely to cause seizures. In either case, the use of flumazenil can carry a substantial risk of seizures. Patients with benzodiazepine overdose respond well to supportive care. Thiamine should be administered when dextrose is given to nutritionally compromised, alcoholic patients with altered mental status (100 mg in the maintenance intravenous line is sufficient and safe).

A complete overdose history is required, particularly when the ingested agent is unknown or the patient is suicidal (Box 145-1). Valuable clues often come from unexpected sources, such as the patient’s previous medical records, the pharmacy where prescriptions were filled, or the prescribing physician as listed on the patient’s prescription bottles. Whenever possible, field personnel should bring the patient’s medications to the hospital with them. If the ingested agent is a hazardous chemical (e.g., pesticide) that might endanger hospital personnel, it should be brought to the hospital in an airtight container or secured at the scene. Precise product identification information must be ascertained so that a hazardous materials reference system can be consulted. When it is suspected that the contents of the container are not the original product, the substance should be checked against the product label. It is easy to confuse the different types of chemical agents with agents with similar names found in many homes, and some may have specific properties that affect treatment. In rare cases, overdose patients may deliberately attempt to deceive caregivers by hiding the ingested agents.

Vital signs, including pulse oximetry, are important in the diagnosis of poisoning and should be measured accurately and repeatedly as indicated. At least one measurement of temperature should be included. Respirations should be counted, not estimated. A cardiac monitor or 12-lead electrocardiogram should be evaluated for QRS and QT intervals, morphology, and rhythm. The physical examination in a comatose patient should ensure that concomitant treatable conditions (e.g., intracranial hemorrhage and central nervous system [CNS] infection) are not missed. Focal neurologic findings could be possible indicators of intracranial catastrophe or severe head trauma.

The pupillary examination may give misleading information. Some opioid agonists, especially propoxyphene and pentazocine, may not produce the characteristic miosis of opioid

---

**SECTION TWO • Toxicology**
Obtaining an Overdose History

- Obtain all prescription bottles and other containers when possible. Perform a pill count. Be sure that the bottles contain the medications listed. Identify any unknown tablets.
- Contact the prescribing physician(s) or the pharmacy as listed on the bottles to determine previous overdoses or other medications that the patient may have available. Identify underlying medical and psychiatric disorders and medication allergies. Review past medical records.
- Talk to the patient’s family and friends in the emergency department. If necessary, call the patient’s home to ask questions of others. The persons providing the important elements of the history should be identified in the chart.
- Search the patient’s belongings for drugs or drug paraphernalia. A single pill hidden in a pocket, for example, may provide the most important clue to the diagnosis.
- Have family members (or the police) search the patient’s home, including the medicine cabinet, clothes drawers, closets, and garage; such searches may also provide clues that make the diagnosis. This has the added benefit of involving the family in the patient’s care.
- Always look for track marks on the patient. Consider body packing or body stuffing.

intoxication. When multiple drugs are ingested, the expected pupillary findings related to any particular agent may be modified or absent.

Physical stigmata of intravenous drug use (track marks) should be sought in both usual (e.g., antecubital fossa) and unusual (e.g., under the tongue and top of the feet) locations. A critical condition of unknown cause may be a result of “body packing” or “body stuffing,” complicated by rupture of packets of cocaine, heroin, or amphetamines (see Chapter 152). Rectal, vaginal, and radiographic examination of the abdomen should be performed in these circumstances.

Other important physical findings are evidence of aspiration or noncardiogenic pulmonary edema on chest auscultation. Bowel sounds may be increased or decreased if agents affecting the cholinergic nervous system have been ingested. A rectal examination to detect melena or hematochezia may also provide evidence of suicidal ingestion of anticoagulant medication.

Unusual odors of the patient’s breath, skin, clothing, vomitus, or nasogastric aspirate may also provide useful diagnostic clues (Table 145-1).1 The absence of such odors, however, should not be taken as evidence that the agents listed are not present.

Toxic Syndromes and Antidotes

The term toxidrome refers to a syndrome or constellation of physical findings that can be attributed to a specific class of toxins and can provide important clues to narrow the differential diagnosis.2 The general rules outlined here have many exceptions, and polydrug overdoses may result in overlapping and confusing mixed syndromes. Nevertheless, this approach may confirm the history, provide the clinician with a starting point for management, and suggest useful laboratory tests. The most common toxidromes are the anticholinergic syndrome, sympathomimetic syndrome, opioid/sedative/ethanol syndrome, cholinergic syndrome, and serotonin syndrome (Table 145-2).

The anticholinergic syndrome occurs frequently because many common medications and plants have anticholinergic properties. Anticholinergic CNS poisoning causes mild temperature elevation and acute delirium with mumbling speech and typical “picking movements” of the fingers. Suppression of cholinergic inhibition of the heart rate leads to tachycardia. Inhibition of the secretory functions of the integument causes dry mouth and skin, and the face is typically flushed. Unopposed sympathetic drive of the ciliary apparatus causes wide papillary dilation. Most patients recover with supportive therapy, but the delirium may last a day or more. Physostigmine may be a useful antidote in carefully selected patients and quickly resolves the delirium. It should not be used with a possible cyclic antidepressant overdose where it is associated with asystole.

The sympathomimetic syndrome is usually seen after acute or chronic abuse of cocaine, amphetamines, or decongestants (e.g., phenylpropanolamine). Patients may be delusional; amphetamine, in particular, may cause complicated, intricate, and paranoid delusions. Seizures may occur, and the postictal state can contribute to the altered mental status. Blood pressure is usually elevated, the pulse is rapid (except with pure alpha-adrenergic agonists, which can cause reflex bradycardia), the pupils are dilated, and piloerection may be seen. In massive overdoses of sympathomimetic agents, cardiovascular collapse can occur with the development of shock and wide-complex dysrhythmias. This clinical picture can mimic that of overdose of cardioactive drugs or cyclic antidepressants. In contrast to the diaphoresis seen with anticholinergic syndrome, the skin in sympathomimetic syndrome is dry.

An extreme presentation of sympathomimetic excess can be excited delirium (Box 145-2). In this state, patients are agitated, hyperthermic, violent, and possess “superhuman strength.” Frequently, many security personnel are required to control these individuals. These individuals may have a severe metabolic acidosis and hyperkalemia, which can cause sudden cardiovascular collapse. It is critical to sedate these patients and control hyperthermia aggressively while treating their acidosis and hyperkalemia simultaneously.

All sedative/hypnotic agents, when taken in sufficient dosage, cause general anesthesia with a complete loss of awareness and reflex activity. The CNS depressant (opioid/sedative/ethanol) syndrome is the most common toxic syn-

Common Toxic Syndromes (Toidromes)

| Anticholinergic | Common signs | Delirium with mumbling speech, tachycardia, dry flushed skin, dilated pupils, myoclonus, slightly elevated temperature, urinary retention, decreased bowel sounds. Seizures and dysrhythmias may occur in severe cases.
| Common causes | Antihistamines, antiparkinsonians, atropine, scopolamine, amantadine, antipsychotics, antidepressants, antispasmodics, mydriatics, muscle relaxants, many plants (e.g., jimson weed, Amanita muscaria) |
| Sympathomimetic | Common signs | Delusions, paranoia, tachycardia (or bradycardia with pure alpha-agonists), hypertension, hyperpyrexia, diaphoresis, piloerection, mydriasis, hyper-reflexia. Seizures, hypotension, and dysrhythmias may occur in severe cases.
| Common causes | Cocaine, amphetamine, methamphetamine and its derivatives, over-the-counter decongestants (phenylpropanolamine, ephedrine, pseudoephedrine). In caffeine and theophylline overdoses, similar findings, except for the organic psychiatric signs, result from catecholamine release. |
| Opioid/Sedative/Ethanol | Common signs | Coma, respiratory depression, miosis, hypotension, bradycardia, hyperthermia, pulmonary edema, decreased bowel sounds, hyporeflexia, needle marks. Seizures may occur after overdoses of some narcotics (e.g., propoxyphene). |
| Common causes | Narcotics, barbiturates, benzodiazepines, ethchlorvynol, glutethimide, methyprylon, methaqualone, meprobamate, ethanol, clonidine, guanabenz |
| Cholinergic | Common signs | Confusion, central nervous system depression, weakness, salivation, lacrimation, urinary/fecal incontinence, gastrointestinal cramping, emesis, diaphoresis, muscle fasciculations, pulmonary edema, miosis, bradycardia/tachycardia, seizures |
| Common causes | Organophosphate and carbamate insecticides, physostigmine, edrophonium, some mushrooms |

Toxins Causing Delirium

Table 145-2

| Anticholinergics | Delirium with mumbling speech, tachycardia, dry flushed skin, dilated pupils, myoclonus, slightly elevated temperature, urinary retention, decreased bowel sounds. Seizures and dysrhythmias may occur in severe cases. |
| Lithium | Antihistamines, antiparkinsonians, atropine, scopolamine, amantadine, antipsychotics, antidepressants, antispasmodics, mydriatics, muscle relaxants, many plants (e.g., jimson weed, Amanita muscaria) |
| MAOIs | | |
| Mushrooms with muscinol/ibotenic acid | | |
| Phencyclidine | | |
| Salicylates | | |
| Sedative withdrawal | | |
| Solvents | | |
| Steroids | | |
| Sympathomimetics (cocaine, amphetamines) | | |

MAOIs, monoamine oxidase inhibitors.

dromes seen in the emergency department, and a depressed sensorium is its hallmark. Mixing agents in this class (e.g., ethanol and benzodiazepines) is common. As the drugs are absorbed at higher doses, the patient becomes increasingly obtunded, the deep tendon reflexes diminish, and, finally, the vital signs deteriorate as medullary drive of respiration and cardiovascular function is attenuated.

Respiratory depression is particularly pronounced with opioid overdose, and the respiratory rate is often diminished before decreases in blood pressure or pulse occur. The diagnosis of opioid overdose is confirmed by the use of naloxone (Narcan) or nalmefene (Revex) in adequate doses. Naloxone has an elimination half-life of 1.1 hours, whereas that of nalmefene is 10.8 hours. Nalmefene is especially useful when the offending opioid has a very long elimination half-life (e.g., methadone, with a half-life of 15–40 hours). Close observation, investigation of alternative causes of depressed mental status when suggested by the clinical course, and airway intervention when indicated are the keys to successful management. Comatose patients often present without a history and need to be managed aggressively, securing the airway when needed.

These patients may need basic labs and head CT if their presentation or course is suspicious for stroke, infection, or head trauma while considering a drug overdose alone or in combination with one of these medical conditions. A serum ethanal level that is not commensurate with the level of CNS depression raises suspicion of intracranial injury, hemorrhage, or infection.

The cholinergic syndrome is uncommon but important to recognize because lifesaving treatment is available. Cholinergic syndrome causes the patient to be “wet,” as opposed to the anticholinergic syndrome, which causes the patient to be “dry.” The wetness is manifest by profuse sweating and excessive activity of virtually the entire exocrine system, often accompanied by vomiting, diarrhea, and urinary incontinence. The mnemonic SLUDGE is used to recall the specific elements of the syndrome: salivation, lacrimation, urination, defecation, gastrointestinal cramping, and emesis. The CNS (e.g., confusion, coma, and seizures) and the skeletal muscles (e.g., weakness and fasciculations) can also be involved. The pupils are often miotic. Cholinergic syndrome is most frequently caused by organophosphate or carbamate pesticide exposure, which may be through unsuspected dermal contamination. Anticholinergic agents are also the foundation of “nerve agents” such as sarin, which was used in the Tokyo subway attack. Recognition of the syndrome led to the use of atropine and cholinesterase regenerators, with a subsequent good outcome in many patients.

Serotonin syndrome ensues when there is a drug interaction involving the selective serotonin reuptake inhibitors (SSRIs) or an overdose of an SSRI. Fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), and citalopram (Celexa) are commonly used SSRIs. Other drugs that are serotonin reuptake inhibitors (SRIs) also inhibit the reuptake of other neurotransmitters and are therefore not specific. These drugs include venlafaxine (Effexor), nefazodone (Serzone), and mirtazapine (Remeron). Drug interactions between many drugs can cause the serotonin syndrome described in Chapter 159. These drugs include the SSRIs,
SRIs, monoamine oxidase inhibitors (MAOIs), tryptophan, sympathomimetics, tricyclic and other antidepressants, meperidine, dextromethorphan, and lithium. Because of the long-lasting effects of the SSRIs, the syndrome can occur when one of the active agents is ingested even weeks after use of an SSRI has been discontinued.

Serotonin syndrome is characterized by altered mental status, fever, agitation, tremor, myclonus, hyper-reflexia, ataxia, incoordination, diaphoresis, shivering, and sometimes diarrhea. The diagnosis relies on the drug history, and it is difficult to distinguish serotonin syndrome from an overdose of cocaine, lithium, or MAOIs; the neuroleptic malignant syndrome; or thyroid storm. Patients may deteriorate slowly and become critically ill after an apparently benign manifestation.

As possible toxidromes are investigated, the use of specific antidotes should be considered (Table 145-3).

### TOXICOLOGY LABORATORY

A toxicology screen (usually urine, sometimes blood and urine, and occasionally including gastric contents) only rarely results in identification of the ingested agent for three major reasons. First, the laboratory does not attempt to screen for many substances, even commonly ingested agents that are capable of causing critical illness (Box 145-3).8

Second, the urine screen is often performed soon after the ingestion, when the drug concentration is too low for a positive result. Even the drug responsible for life-threatening symptoms (e.g., tricyclic antidepressant) may be negative on the urine screen soon after ingestion. Other drugs, such as γ-hydroxybutyrate, are present relatively briefly in blood and urine and may therefore be negative in samples collected even on the same day.

Third, drugs found on screening may not be those responsible for the initial symptoms, especially if the drugs are not quantified (e.g., benzodiazepines and cocaine parent compound). In such cases, a positive screen may not relate to the patient’s current findings and symptoms. Drugs with a large volume of distribution or high fat solubility may be detected in urine for a long time after the last dose. Cocaine metabolites may be detected for days and marijuana for weeks after the last exposure. Proper interpretation of urine screens requires consideration of the patient’s current clinical condition. In addition, the results of toxicology screens are not usually available until many hours after most of the important treatment decisions are made. Screening results rarely change the clinical management of patients.8 Toxicology screens are often very expensive, and their use is not warranted in most routine drug overdoses. The full toxicology screen is most useful in patients who (1) present with their first psychotic episode or (2) are critically ill for an unknown reason when identification of an otherwise unsuspected toxin may change management.

Alternatives to a full toxicology screen include (1) obtaining discrete drug levels (e.g., acetaminophen, which should be considered in almost all intentional ingestions), (2) a qualitative urine screen for drugs of abuse, or (3) no toxicology tests.89 Quantitative measurements of suspected drugs may be helpful. In the agitated or seizing patient, elevated salicylate, theophylline, or lithium levels would significantly alter the management. Several commercial urine testing kits have a rapid turnaround time, primarily for drugs of abuse. Electrolyte levels help identify metabolic acidosis by the carbon dioxide content (“bicarbonate level”), which should be repeated if low to ensure that the acidosis is resolving. A persistent, unexplained metabolic acidosis should prompt urine examination for oxalate crystals (suggestive of ethylene glycol poisoning), a serum salicylate level, and methanol and ethylene glycol levels. A normal arterial blood gas or electrolyte measurement does not rule out such ingestion because metabolic acidosis is delayed and does not appear until after metabolism of the acids from ethylene glycol/methanol or until after erratic and slow absorption of salicylate. Arterial blood gas measurement is rarely helpful but may confirm when pulse oximetry is misleadingly low with carboxyhemoglobin and methemoglobinemia.

Rhabdomyolysis should be diagnosed by obtaining a serum CK level when there is severe agitation or hyperthermia, or if the patient is thought to have been unresponsive for a prolonged period of time (i.e., by history of presence or pressure sores). A urinary dipstick for blood (myoglobin) and a serum creatine kinase should be checked. Rhabdomyolysis and its treatment are discussed in Chapter 125. Noncardiogenic pulmonary edema on a chest radiograph suggests opioid or salicylate overdose. Selective abdominal radiographs can detect smuggled packets. Some drugs are radiopaque (e.g., heavy

NSAIDs, nonsteroidal anti-inflammatory drugs.
## Table 145-3
### Antidotes Used in the Emergency Department

<table>
<thead>
<tr>
<th>TOxin Used For</th>
<th>Antidote</th>
<th>Dose and Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Acetaminophen</td>
<td>N-acetylcysteine</td>
<td>140 mg/kg PO, then 70 mg/kg q4h for up to 17 doses or 150 mg/kg IV load over 1 hr with 50 mg/kg over 4 hr followed by 100 mg/kg over 16 hr</td>
</tr>
<tr>
<td>Anticholinergics</td>
<td>Physostigmine</td>
<td>1–2 mg IV in adults, 0.5 mg in children over 2 min for anticholinergic delirium, seizures, or dysrhythmias</td>
</tr>
<tr>
<td>Arsenic, lead, and mercury</td>
<td>d-Penicillamine</td>
<td>3–5 mg/kg IM only</td>
</tr>
<tr>
<td>Benzodiazepines</td>
<td>Flumazenil</td>
<td>20–40 mg/kg/day; 500 mg tid in adults; may cross-react with penicillin in allergic patients</td>
</tr>
<tr>
<td>Black widow spider bite</td>
<td>Latrodectus antivenin</td>
<td>One vial by slow IV infusion is usually curative; may cause anaphylaxis</td>
</tr>
<tr>
<td>Beta-blockers</td>
<td>Glucagon</td>
<td>5–10 mg in adults, then infusion of same dose per hour</td>
</tr>
<tr>
<td>Calcium channel blockers</td>
<td>Calcium</td>
<td>1 g calcium chloride IV in adults, 20–30 mg/kg/dose in children, over a few minutes with continuous monitoring. Repeat as needed</td>
</tr>
<tr>
<td>Cyanide</td>
<td>Hydroxycobalamin</td>
<td>5 mg in 100 mL of NS over 15 min. Repeat if necessary</td>
</tr>
<tr>
<td>Cyanide, hydrogen sulfide</td>
<td>Sodium thiosulfate</td>
<td>50 mL of 25% (12.5 g; 1 ampule) in adults; 1.65 mL/kg IV in children</td>
</tr>
<tr>
<td>Ethylene glycol</td>
<td>Digoxin-specific Fab</td>
<td>10–20 vials if patient in ventricular fibrillation; otherwise dose fragments based on serum digoxin concentration or amount ingested</td>
</tr>
<tr>
<td>Ethanol</td>
<td>Pyridoxine</td>
<td>15 mg/kg × 1, then 10 mg/kg q12h × 4, until ethylene glycol &lt; 20 mg/dL. Adjust dose during dialysis</td>
</tr>
<tr>
<td>Iron</td>
<td>Calcium gluconate</td>
<td>3.5 g in 5 oz of KY jelly topical; apply liberally to affected skin</td>
</tr>
<tr>
<td>Isoniazid, hydrazine, and monomethylhydrazine</td>
<td>Pyridoxine</td>
<td>5 g in adults, 1 g in children, if ingested dose unknown; antidote may cause neuropathy in very large doses</td>
</tr>
<tr>
<td>Lead</td>
<td>DMSA (succimer)</td>
<td>Reported useful for arsenic and lead as well; one 100-mg capsule per 10-kg body weight tid for 1 wk, then bid, with chelation breaks</td>
</tr>
<tr>
<td>Methanol</td>
<td>Folate or leucovorin</td>
<td>50 mg IV q4h in adults while patients have serious toxicity</td>
</tr>
<tr>
<td>Methemoglobin-forming agents</td>
<td>Methylene blue</td>
<td>1–2 mg/kg IV, one 10-mL dose of 10% solution (100 mg) is typical for an adult without anemia</td>
</tr>
<tr>
<td>Methanol</td>
<td>Ethanol</td>
<td>Loading dose, 10 mL/kg of 10%; maintenance dose, 0.15 mL/kg/hr of 10%; double rate during dialysis</td>
</tr>
<tr>
<td>Opioids</td>
<td>Nalmefene</td>
<td>2 mg; much longer half-life than naloxone</td>
</tr>
<tr>
<td>Opioids</td>
<td>Naloxone</td>
<td>2 mg; less to avoid narcotic withdrawal, more if inadequate response; same dose in children</td>
</tr>
<tr>
<td>Organophosphates and carbamates</td>
<td>Atropine</td>
<td>Test dose, 1–2 mg IV in adults, 0.03 mg/kg in children; titrate to drying of pulmonary secretions</td>
</tr>
<tr>
<td>Organophosphates and carbamates</td>
<td>Protopam</td>
<td>Loading dose, 1–2 g IV in adults, 25–50 mg/kg in children; adult maintenance, 500 mg/hr or 1–2 g q4–6h</td>
</tr>
<tr>
<td>Organophosphates and carbamates</td>
<td>Fomepizole</td>
<td>15 mg/kg × 1, then 10 mg/kg q12h × 4, until methanol &lt; 20 mg/dL. Adjust dose during dialysis</td>
</tr>
<tr>
<td>Organophosphates and carbamates</td>
<td>Methylenediaminoheptadine</td>
<td>4 mg PO as needed; no parenteral form available; antidote may cause anticholinergic effects</td>
</tr>
<tr>
<td>Rattlesnake bite</td>
<td>CroFab antivenin</td>
<td>Five vials minimum dose by infusion in normal saline; increases in rate dependent on patient tolerance; may cause anaphylaxis</td>
</tr>
<tr>
<td>Sulfonamides</td>
<td>Octreotide</td>
<td>50 µg SC q12h, 5–10 µg/kg/24 hr IV</td>
</tr>
<tr>
<td>Sulfonamides</td>
<td>Olanzapine</td>
<td>100 mg/kg IV or PO loading dose with 25 mg/kg q6h</td>
</tr>
<tr>
<td>Tricyclic antidepressants</td>
<td>Bicarbonate</td>
<td>44–88 mEq in adults, 1–2 mEq/kg in children; best used by IV push and not by slow infusion</td>
</tr>
<tr>
<td>Valproic acid</td>
<td>Carnitine</td>
<td>100 mg/kg IV or PO loading dose with 25 mg/kg q6h</td>
</tr>

metals, phenothiazines, potassium, calcium, and chlorinated hydrocarbons such as chloral hydrate), but radiography is rarely helpful in the evaluation of a poisoned patient except to monitor the decontamination of iron, lead, or body packets.  

**DECONTAMINATION**

Gastric decontamination rarely affects the clinical outcome in the undifferentiated poisoned patient and should not be undertaken routinely.  

Children with accidental ingestion rarely consume enough drug to cause symptoms, and the fatality rate for those cases is less than 0.0025%.  

Decontamination with activated charcoal (AC) has not been proven to improve outcome either in the undifferentiated overdose patient or in any specific poisoning. It should be considered only in the small number of cases in which it is early enough (<1 hour after ingestion) to make a difference or for medications of a type and in quantities that may be truly toxic beyond the requirement for supportive care. These medications include beta-blockers, calcium channel blockers, and cyclic antidepressants. Because gastric decontamination has not been shown to be of benefit and carries some risk, particularly if a nasogastric tube is required, it should be used selectively and with caution, if at all.

If charcoal is used, 50 g of an oral slurry of AC is usually sufficient. If the patient is obtunded or uncooperative and the benefits of AC administration are thought to outweigh the risks (principally aspiration), intubation should be considered and the AC can be administered through a nasogastric tube. A cathartic, such as sorbitol, was formerly recommended to speed AC transit through the gut, but cathartics have never been shown to be of benefit and, in general, should be avoided. Repeated doses of sorbitol can cause dehydration. Agents that do not adsorb to charcoal include ions (e.g., acids and alkalies, lithium, borates, and bromides), hydrocarbons, metals (e.g., iron), and ethanol, but adsorption to charcoal does not equate to lesser toxicity or improved outcome.

Whole-bowel irrigation with a polyethylene glycol solution, although of no proven outcome benefit, may be used in certain cases of severe, recent ingestion of lithium or metals such as iron or lead or in patients with ingestion of sustained-release formulations of highly toxic drugs. It has also been used to aid in the evacuation of drug packets from body packers. Whole-bowel irrigation is unpleasant for both patient and staff, and it should be considered only after consultation with a toxicologist. It is typically done by placing a nasogastric tube and continuously infusing a bowel preparation solution, such as Go-Litely, beginning at 1 or 2 L/hour and continued until the rectal effluents are clear.

Gastric lavage is rarely, if ever, indicated and should be considered only when a patient is seen within a few minutes (<1 hour) after the ingestion of a highly toxic substance (e.g., calcium channel blocker and cyclic antidepressant). Gastric lavage has not been shown to improve the clinical course or outcome of undifferentiated poisoned patients, although it has not been studied in selected higher risk populations. In the rare circumstances in which gastric lavage is performed, a large (30-F or greater) orogastric tube is used, and specially designed lavage systems with large-bore tubes are available for this purpose. Syrup of ipecac has not been shown to change the clinical outcome of poisonings and is no longer used in emergency departments and rarely in out-of-hospital settings. Its use has been restricted because of its abuse by patients with bulimia.

Exposure of the eye to caustic chemicals and irritants requires immediate irrigation with large amounts of water or readily available fluid, as outlined in Chapter 151. It is more important to begin the irrigation immediately, preferably before transfer to the emergency department. Exposure to a gas does not require decontamination because the patient and rescuers are not at risk once the patient is removed from the toxic environment. The exception is when the patient’s skin or clothing is contaminated with a liquid that is evaporating. The most important intervention to limit dermal exposure is to remove all clothing as soon as possible, ideally at the scene. Skin should be irrigated with warm water and with attention to skin folds and other areas that might be missed. This includes the axilla, beneath nails, behind the knees, the genitalia, and in the scalp. For hydrocarbons or solvents, soap can be added. The skin should not be abraded with overly aggressive scrubbing, which could increase skin absorption. Ideally, skin decontamination occurs as soon as possible after exposure, at an out-of-hospital site before transport.

**DISPOSITION AND CONSULTATION**

The decision to admit a patient is not difficult when the patient manifests serious toxicity. When the patient is minimally symptomatic but has ingested a potentially dangerous substance, the decision is more difficult. Identification of an agent that causes a particular risk for the patient, especially cardiovascular instability, seizures, or respiratory depression, generally mandates admission to the hospital or to an observation unit in the emergency department. A 6-hour period of observation for a minimally symptomatic patient is usually sufficient, except for some extended-release preparations. Patients with cardiac dysrhythmia, conduction disturbance, altered mental status requiring intubation, or the need for frequently titrated agents (e.g., pressors) should be admitted to the intensive care unit or a monitored inpatient unit. If the patient is acutely suicidal, a sitter or secure environment may be required.

Regional poison centers use a single nationwide toll-free number, 1-800-222-1222, and can provide specific, current advice, especially for more esoteric or unfamiliar poisons. Consultation with a medical toxicologist is particularly helpful when an uncommon agent has been ingested, the patient is not following the anticipated clinical course, or specific interventions such as administration of antibody therapy or dialysis are contemplated.

**KEY CONCEPTS**

- A thorough history from many sources is the key to toxicologic diagnosis.
- Common toxidromes should guide judicious use of antidotes.
- Minimally symptomatic patients do not benefit from toxicology screening or extensive laboratory investigation.
- Good supportive care is the key to management.
- Activated charcoal is rarely indicated in overdose, and other methods of gut decontamination (gastric lavage and whole-bowel irrigation) are virtually never helpful. Activated charcoal may decrease absorption of many drugs, but it has not been shown to improve outcome, and its use should be carefully weighed against potential complications.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Acetaminophen is one of the most commonly used antipyretic and analgesic agents throughout the world. Acetaminophen may be found as an isolated product or in combination medications for the treatment of cold symptoms, pain, and headache. Given its widespread use and availability, acetaminophen toxicity is a concern in all intentional ingestions as well as in cases of therapeutic misadventures and drug abuse. Acetaminophen toxicity is one of the leading causes of hospital admission, antidotal use, and patient fatalities among ingested substances in the United States.

Through significant study and experience, established protocols for the assessment and management of acute acetaminophen ingestion exist. Despite this, controversy continues to exist, and with new formulations in development, the management of acetaminophen ingestion promises to continue to evolve.

PRINCIPLES OF DISEASE

Acetaminophen is absorbed rapidly, with peak plasma concentrations generally occurring within 1 hour and complete absorption within 4 hours. Once absorbed, acetaminophen inhibits prostaglandin E2 (PGE2) synthesis, leading to antipyresis and analgesia. Inhibition of PGE2 synthesis is either by direct COX-2 inhibition or inhibition of membrane-associated prostaglandin synthase.

After therapeutic ingestion, acetaminophen is primarily metabolized by conjugation with glucuronide (40–67%) and sulfate (20–46%) into nontoxic metabolites that are excreted in the urine (Fig. 146-1). A small percentage (<5%) is oxidized by cytochrome P450 2E1 (CYP2E1) (and to a lesser extent 1A4 and 3A4) to a highly cytotoxic metabolic intermediary, N-acetyl-p-benzoquinonimine (NAPQI). In therapeutic doses, NAPQI is short-lived, combining rapidly with glutathione and other thiol-containing compounds to form nontoxic metabolites that are excreted in the urine. With typical therapeutic acetaminophen dosing, glutathione stores and the ability to regenerate glutathione easily keep up with NAPQI production.

After large ingestions or repeated supratherapeutic ingestions, the amount of NAPQI produced begins to outstrip glutathione stores and the liver’s ability to regenerate glutathione, leading to unbound NAPQI. The highly reactive electrophile NAPQI covalently binds to critical cell proteins in the liver, which initiates a cascade of events that lead to hepatic cellular death. Renal injury may also occur with or without liver injury and may be mediated by renal CYP enzymes or activation of prostaglandin synthase.

Acetaminophen-induced liver damage initially occurs in hepatic zone III (centrilobular) because oxidative metabolism is concentrated in this area. With severe toxicity, necrosis of the entire liver parenchyma may occur. The clinical effects of severe acetaminophen toxicity are the result of severe fulminant liver failure rather than a direct acetaminophen effect. These effects include multiorgan failure, systemic inflammatory response syndrome, hypotension, cerebral edema, and death.

The principal therapy for acetaminophen toxicity is N-acetylcysteine (NAC), which is effective via two separate mechanisms. Soon after overdose, NAC serves as a glutathione precursor and a sulfur-containing glutathione substitute (see Fig. 146-1), thereby detoxifying NAPQI and avoiding subsequent hepatotoxicity. In addition, NAC may decrease NAPQI formation by enhancing acetaminophen conjugation with sulfate to nontoxic metabolites.

Even after acetaminophen hepatotoxicity is evident, NAC acts as a free-radical scavenger and an antioxidant and alters hepatic microcirculation and oxygen delivery. Patients with acetaminophen-induced hepatic failure, intravenous (IV) NAC has been shown to decrease the rates of cerebral edema, hypotension, and death even when no acetaminophen remains.

CLINICAL FEATURES

Acetaminophen toxicity leads to hepatic injury, which can progress to hepatic failure and renal failure. Early after acute acetaminophen ingestion, patients may be asymptomatic or have mild nonspecific symptoms (e.g., nausea, vomiting, anorexia, malaise, diaphoresis) (Table 146-1). Liver injury becomes evident after a period of 8 to 36 hours as an elevation in aspartate aminotransferase (AST). Once liver injury has begun, patients may develop right upper quadrant (RUQ) pain or tenderness, vomiting, and jaundice. AST concentrations continue to rise and usually peak in 2 to 4 days, corresponding to maximal liver injury. Alanine aminotransferase (ALT), prothrombin time (PT), and bilirubin typically begin to rise and peak shortly after AST values. In severe toxicity, AST, ALT, and the PT may all be elevated within 24 hours (Fig. 146-2). With maximal liver injury, patients may develop signs and symptoms consistent with fulminant liver

failure, including metabolic acidosis, coagulopathy, and hepatic encephalopathy. Death may occur from hemorrhage, adult respiratory distress syndrome, sepsis, multiorgan failure, or cerebral edema. The risk of renal injury increases with the severity of hepatic injury, occurring in less than 2% of patients without hepatotoxicity and in 25% of patients with severe hepatotoxicity.20-22

If patients recover, transaminases return to baseline levels over a 5- to 7-day period, although complete histologic resolution of liver injury may take months. Once histologic recovery is complete, there are no long-term sequelae to the liver and patients are not at risk for chronic hepatic dysfunction.23

Diagnostic Strategies

The primary goals of patient assessment after acetaminophen exposure are the determination of the patient’s risk, diagnostic testing, and treatment with the antidote NAC when appropriate.

Acetaminophen exposures may be classified as acute or chronic, and each type requires different testing and risk assessment. An acute ingestion is generally considered to be a single ingestion, arbitrarily defined to be occurring within a 4-hour period. All other ingestions, including accidental repeated supratherapeutic ingestions and intentional ingestions spread over longer than 4 hours, can be considered to be chronic.

Risk Assessment with Acute Acetaminophen Ingestion

The initial diagnostic strategy of an acute ingestion is well established. The first step is to determine the patient’s risk of acute acetaminophen exposure. Patients who report an acute
Intentional ingestion of acetaminophen require laboratory risk stratification regardless of the reported amount ingested. It is likely that significantly greater than 150 mg/kg in an acute ingestion must be consumed before significant liver toxicity is evident; however, historical factors may not be reliable. A serum acetaminophen concentration may be considered in all intentional overdoses because approximately 1.4 to 8.4% of patients with intentional ingestions who deny acetaminophen ingestion actually have a detectable concentration.24-26

Once a suggested exposure to acetaminophen is established, the next step is to establish a time of ingestion. If possible, this information should be corroborated by others. If no accurate time of ingestion can be determined, a worst-case scenario should always be considered (e.g., the last time the patient was seen prior to the ingestion).

Once a patient is determined to be at risk and a time of ingestion established or estimated, the next step is to determine a serum acetaminophen concentration 4 hours post-ingestion, or as soon as possible after 4 hours. The serum acetaminophen concentration and the time of ingestion determine the need for antidotal therapy by plotting the serum acetaminophen concentration against the time since ingestion on the treatment nomogram (Fig. 146-3), an adaptation of the Rumack-Matthew nomogram.27 If the serum acetaminophen concentration is on or above the treatment line (that starts at 150 µg/L at 4 hr and decreases to 4.7 µg/L at 24 hr), then antidotal treatment with NAC should be initiated immediately. If the serum acetaminophen concentration is below the treatment line and the worst-case scenario has been taken for the time of ingestion, then the patient requires no antidotal therapy.28-30 Use of the treatment line is a highly sensitive approach and may be used for all acute ingestions.

Measurement of serum acetaminophen concentration prior to 4 hours is typically not necessary. It is possible that a serum acetaminophen concentration less than 10 µg/L between 1 and 4 hours after ingestion may exclude significant ingestion of acetaminophen; however, there are little data on which to base this conclusion. Absorption of acetaminophen may not be complete prior to 4 hours, and any serum acetaminophen concentration greater than 10 µg/L is difficult to interpret. Finally, serum acetaminophen concentrations measured prior to 4 hours cannot be plotted on the treatment nomogram. Fortunately, there is little need to treat patients prior to 6 to 8 hours after ingestion, as patients treated with NAC up to 6 hours after ingestion have no increased risk of hepatotoxicity regardless of their serum acetaminophen concentration.31 For most patients, the risk of hepatotoxicity does not significantly increase unless NAC is delayed for 8 hours or longer after ingestion.28,31 This is generally enough time for a serum acetaminophen concentration to be drawn at 4 hours and the laboratory evaluation to be completed. For patients at risk whose serum acetaminophen concentration cannot be obtained prior to 6 to 8 hours after ingestion, a loading dose of NAC should be considered.

Risk Assessment with Chronic Ingestion

If the ingestion is a repeated or chronic exposure, risk assessment is somewhat more complex, and the treatment nomogram cannot be used. The initial steps include determining if the patient is at risk for hepatotoxicity, evaluating the patient by measuring a serum acetaminophen concentration and an AST, and initiating therapy with NAC.

The risk of hepatotoxicity from chronic ingestion of acetaminophen is increased with both: (1) an increasing total dose of acetaminophen, and (2) a longer duration over which it has been ingested in supratherapeutic quantities. With this in mind, laboratory testing for serum acetaminophen concentration and AST should be initiated in any patient who fits the criteria in Table 146-2.32

Ingestion of therapeutic amounts of acetaminophen appears to be quite safe.29,33 However, rare reports of transaminitis and liver injury during therapeutic dosing suggests that some patients may be at increased risk for liver injury, possibly due to genetic variation or to specific risk factors.34 Patients who chronically ingest isoniazid (INH)35,36 or ethanol37-40 may have increased CYP2E1 activity and, therefore, be at higher risk for chronic acetaminophen toxicity. Similarly, patients who have prolonged fasting (e.g., malnourished, AIDS, severe prolonged vomiting)41 and children with febrile illnesses42-46 have been suggested to have higher risk. All of these risk factors are controversial and require additional study. Given that we are unable to accurately predict the rare patient at high risk, patients who have symptoms consistent with liver injury (e.g., RUQ pain or tenderness, jaundice) with the intake of
acetaminophen merit risk determination regardless of the amount that they reportedly ingest.

Once serum acetaminophen concentration and AST are obtained, further risk assessment is necessary. Conceptually, patients with chronic ingestions may benefit from antidotal therapy if they have evidence of liver injury or if they have evidence of acetaminophen excess that may lead to liver injury. With this in mind, patients with chronic supratherapeutic acetaminophen exposure with significant elevations of AST (e.g., >200 IU) should be treated with NAC regardless of their serum acetaminophen concentration. A higher cutoff for AST (e.g., twice normal, or >120 IU) has been suggested and may be safe, but is unstudied. In patients with an AST that is not elevated (e.g., <50 IU), NAC should be initiated if their serum acetaminophen concentration is higher than expected. After a typical therapeutic dose of acetaminophen, serum acetaminophen concentration peaks below 30 µg/L and is less than 10 µg/L at 4 hours.

All patients who do not require antidotal therapy should be educated to return to the emergency department if they develop signs of hepatotoxicity (e.g., RUQ abdominal pain, vomiting, jaundice).

**Risk Assessment in Pregnant Women**

Fetal acetaminophen toxicity is rare, but adverse outcomes have been reported in all stages of pregnancy. Acetaminophen crosses the placenta and may be present in concentrations in the fetus that are as high as, or higher than, those in the mother. In the early gestational period, acetaminophen toxicity can be associated with fetal death. CYP enzymes appear in the fetus during the second trimester, and activity increases with gestational age, which may put the maturing fetus (e.g., third trimester) or newborn at risk of toxicity.

The risk assessment and diagnostic approach to pregnant women, however, is the same as for nonpregnant women. In acute overdoses, a serum acetaminophen concentration should be drawn and plotted on the treatment nomogram. NAC therapy should be initiated if the serum acetaminophen concentration plots above the treatment line. With chronic exposure, if either the AST is above 50 IU or the serum acetaminophen concentration is above expected, NAC therapy should be initiated.

**MANAGEMENT**

Treatment of acetaminophen toxicity might sometimes include limiting gastrointestinal (GI) absorption, but the mainstays of management are providing supportive care and initiating NAC therapy when indicated.

**Limiting Gastrointestinal Absorption**

Gastric emptying by lavage is rarely indicated in cases of isolated acetaminophen overdose because of the very rapid absorption of acetaminophen and the availability of an effective antidote. Early gastric emptying may be considered in cases of recent, life-threatening coingestions (see Chapter 145).

Activated charcoal (AC) effectively binds acetaminophen, but there is no evidence that administration of AC translates into improved clinical outcomes. One small study suggests that, when given early (e.g., <2 hr after ingestion), AC may decrease the risk that a patient requires admission for antidotal therapy, and some evidence exists for AC use more than 4 hours after ingestion. However, methodologic issues limit the strength of these observations. Overall, there is insufficient evidence to support a recommendation for the routine use of AC in cases of acetaminophen poisoning presenting to the emergency department.

In those rare circumstances in which a clinician may want to give both oral (PO) AC and PO NAC simultaneously (e.g., decision to use PO NAC immediately after AC was given), absorption of the NAC is optimized by delaying the NAC for 1 to 2 hours, if possible. Overall, though, the fact that NAC is of proven value in treating acetaminophen poisoning, and AC is not, is further argument to avoid using AC in patients with acetaminophen overdose. Both NAC and AC can increase vomiting.

**N-Acetylcysteine**

When indicated, NAC should be administered as early as possible. Delay of administration of NAC longer than 6 to 8 hours after ingestion increases the risk of hepatotoxicity (Fig. 146-4). Once the need for NAC is determined, it can be administered PO or IV. Both methods are efficacious in most situations, with advantages and disadvantages for each. All

![Figure 146-4. Risk of liver injury (aspartate transaminase > 1000 IU) based on initial acetaminophen concentration and time to administration of oral N-acetylcysteine. (Adapted from Rumack BH: Acetaminophen hepatotoxicity: The first 35 years. J Toxicol Clin Toxicol 40:3, 2002.)](Image)
formulations of NAC (PO or IV) are very effective when started within 6 to 8 hours of ingestion. During this period, NAC’s main role is to prevent hepatotoxicity by detoxifying NAPQI and decreasing NAPQI production. The risk of liver injury (i.e., AST > 1000 IU) in this group when treated with NAC is less than 4% and the mortality rate approaches zero (see Fig. 146-4).

Both PO and IV NAC are equally effective in treating patients who present 8 to 24 hours after ingestion, although the overall rate of liver injury (i.e., AST > 1000 IU) in this group is significantly higher (approximately 30%). Although early studies suggested that the PO formulation might be more effective than IV administration in patients treated 10 to 24 hours after ingestion, the differences between the effectiveness of PO and IV NAC likely reflect the length of therapy and dose of NAC, rather than the route.

Once liver failure (e.g., coagulopathy, encephalopathy, etc.) is evident, however, the IV route is the only route that has been systematically studied. IV NAC decreases the risk of hypotension, cerebral edema, and death in patients with acetaminophen-related hepatic failure. Although PO NAC may be effective in this setting, there is inadequate published data to recommend its use when IV NAC is available.

The main differences between IV and PO NAC are in their side effect profiles (Table 146-3). Approximately 2 to 6% of patients treated with IV NAC develop anaphylactoid reactions, although rates of up to 14 to 18% have been reported in prospective trials. The majority of these symptoms are mild and consist of transient skin rashes and flushing. More severe reactions have been reported in less than 1% of patients and include angioedema, bronchospasm, hypotension, and at least one death. Symptoms typically occur within 30 minutes of the start of the loading infusion. These anaphylactoid reactions are dose-, rate-, and concentration-dependent.

Anaphylactoid reactions are much less frequent with PO NAC. Skin rash, serious systemic reactions, and anaphylactic reactions are rarely reported with the PO formulation. However, up to 50% of patients receiving PO NAC vomit, potentially delaying timely antidotal delivery. PO NAC is extremely unpalatable largely due to a “rotten egg” odor and taste. Palatability may be improved by administering NAC diluted with either soda or juice and serving it in a covered container through a straw. Any dose that is vomited within 1 hour of administration should be repeated. Antiemetics (e.g., ondansetron, metoclopramide, etc.) are advisable prior to PO NAC dosing, but there are little data about effectiveness of this approach.

Anaphylactoid reactions to IV NAC are typically mild (e.g., flushing) and occur during the initial 15- to 60-minute infusion. Mild reactions can be managed with antihistamines (e.g., IV diphenhydramine) without stopping the infusion. Serious reactions can be managed by slowing or pausing the infusion, giving a fluid bolus, and administering diphenhydramine or IV glucocorticoids if necessary. Epinephrine is rarely required. Although these reactions require close observation and treatment as necessary, they do not preclude subsequent doses.

### N-Acetylcysteine in Pregnancy

Treating the mother with NAC is safe and effective, and NAC effectively crosses the placenta. Administration of IV NAC to the mother has the theoretical advantage of increased NAC delivery to the fetus compared with PO NAC. IV administration circumvents first-pass metabolism, presumably exposing the fetal circulation to higher maternal serum concentrations. Once NAC is initiated, there is a paucity of published data to determine an appropriate length of treatment. All large published studies have continued therapy for 72 hours and, therefore, it is difficult to recommend a shorter protocol in the absence of published experience.

### Duration of Therapy

There are two well-established protocols for NAC administration: a 72-hour PO protocol and a 21-hour IV protocol. At the completion of these protocols, NAC may be discontinued if the metabolism of acetaminophen is complete (i.e., serum acetaminophen concentration < 10 µg/mL) and there is no evidence of liver injury (AST concentration normal). However, the endpoint does not rely solely on the predetermined length of a protocol and should be extended if there is significant liver injury (AST concentration greater than normal) or acetaminophen metabolism is incomplete (serum acetaminophen concentration > 10 µg/mL). If extended, NAC therapy may then be discontinued once evidence of liver injury has resolved (e.g., encephalopathy and coagulopathy have resolved and AST is approaching normal) and acetaminophen is undetectable. A variety of “short-course” protocols exist, and all follow the logic described earlier; NAC may be discontinued once acetaminophen metabolism is complete and there is an absence of, or resolution of, acetaminophen-induced liver injury. Decreasing the duration of a well-established protocol should be done thoughtfully and only in low risk patients (e.g., patients treated with NAC within 6–8 hr).

### Supportive Care

Supportive care includes management of nausea and vomiting, hepatic injury, and renal dysfunction. Treatment of these problems is based on general treatment principles and is not acetaminophen-dependent (see Chapter 88).

### DISPOSITION

Asymptomatic patients who fit the criteria for treatment should be treated with NAC and can be admitted to a medical ward or emergency department observation unit. The motivation behind any ingestion needs to be evaluated, and psychiatric consultation may be obtained when appropriate.

Patients showing evidence of severe hepatotoxicity and those at risk for fulminant hepatic failure may need to be admitted to a monitored bed in an intensive care unit, preferably a liver failure unit. These patients require frequent neurologic checks, monitoring of vital signs, and laboratory studies.

If a patient presents with established hepatotoxicity transfer to a higher level center that specializes in the care of patients with liver failure may be advisable, as is the case for any other patient presenting with liver failure. Clinical predictors of severe hepatic failure are listed in Table 146-4.

### KEY CONCEPTS

- Acetaminophen concentration should be measured in cases of unknown or mixed overdoses. Acetaminophen is relatively clinically silent until serious hepatotoxicity ensues.
- Repeated supratherapeutic dosing of acetaminophen can lead to life-threatening toxicity.
- The treatment nomogram for NAC applies only to acute ingestions; the acetaminophen concentration at 4 hours postingestion is used to determine whether NAC therapy is indicated.
- For maximum benefit, NAC treatment should not be delayed beyond 8 hours after ingestion. If more than 6 to 8 hours has passed since ingestion, treatment should be started immediately, pending further assessment of the amount of ingestion and likelihood of hepatotoxicity.
- Late or prolonged administration of NAC is beneficial even after hepatotoxicity is evident.

Perspective

The incidence of aspirin (acetylsalicylic acid [ASA]) overdose and related childhood deaths has decreased significantly in recent years. Reasons include pediatricians’ preference for acetaminophen preparations, the Food and Drug Administration’s mandate limiting 36 tablets of baby ASA to each bottle, and the use of child-resistant caps.

Unfortunately, the severity of this poisoning may be underestimated due to lack of familiarity with the clinical picture. Salicylate toxicity can cause metabolic acidosis, seizure, hyperthermia, pulmonary edema, cerebral edema, renal failure, and death. Morbidity and mortality are increased by delayed diagnosis in elderly patients with chronic medical problems and in young patients diagnosed with an acute illness.¹

Principles of Disease

Pharmacokinetics

Salts of salicylic acid are rapidly absorbed intact from the gastrointestinal tract, with appreciable serum concentrations occurring within 30 minutes. Two thirds of a therapeutic dose is absorbed in 1 hour, and peak levels occur in 2 to 4 hours. Serum concentrations may rise for more than 12 hours after large ingestions (which may delay gastric emptying) or ingestions of enteric capsules.²

In the intestinal wall, liver, and red blood cells, aspirin is hydrolyzed to free salicylic acid, which reversibly binds to albumin (which contains a genetically determined variable number of salicylate-binding sites). In the liver, salicylate is conjugated with glucuronic acid and glycine (Fig. 147-1). A small fraction is hydroxylated. Free salicylate and its conjugates are eliminated by renal excretion. At therapeutic salicylate concentrations, elimination follows first-order kinetics, and excretion is proportional to salicylate concentration. When serum salicylate concentrations are greater than 30 mg/dL, however, elimination follows zero-order kinetics, and the metabolic rate is constant. The metabolic pathways become saturated, and the pH-sensitive urinary excretion of salicylic acid determines the half-life (which may approach 15–30 hr with toxic doses).²

Pathophysiology

Acid-Base Disturbances and Metabolic Effects. Salicylate stimulates the medullary respiratory center early and increases the sensitivity of the respiratory center to pH and carbon dioxide partial pressure (P\text{CO}_2). Hyperventilation develops early, then subsequently becomes a compensatory mechanism to the metabolic acidosis. Prolonged high serum concentrations eventually depress the respiratory center. Respiratory alkalosis is compensated for by buffering of the hemoglobin-oxyhemoglobin system, the exchange of intracellular hydrogen ions for extracellular cations, and the urinary excretion of bicarbonate. Loss of bicarbonate decreases buffering capacity and intensifies the metabolic acidosis.³,⁴

Toxicity results primarily from interference with aerobic metabolism by uncoupling of mitochondrial oxidative phosphorylation. Inhibition of the Krebs dehydrogenase cycle increases production of pyruvic acid and increases conversion to lactic acid. Increased lipid metabolism increases production of ketone bodies. Metabolic rate, temperature, tissue carbon dioxide, and oxygen consumption are increased. Tissue glycolysis predisposes to hypoglycemia. (Hepatic gluconeogenesis and release of adrenaline may cause the less common hyperglycemia.) Inefficiency of anaerobic metabolism results in less energy being used to create ATP, and energy is released as heat, causing the hyperthermia frequently seen in salicylate poisoning.⁴

Only nonionized particles can cross the cell membrane and accumulate in the brain and other tissues. Because ASA has a low pHₐ,³,⁵ the majority of salicylate is ionized and little salicylate enters tissues at the physiologic pH of 7.4. However, as pH decreases, more particles become un-ionized, cross the cell membrane and blood-brain barrier, markedly increasing the movement of salicylate into the tissues and central nervous system (CNS).³,⁵

Fluid and Electrolyte Abnormalities

Significant potassium loss in salicylate toxicity is caused by (1) vomiting, secondary to stimulation of the medullary chemoreceptor trigger zone; (2) increased renal excretion of sodium, bicarbonate, and potassium as a compensatory response to the respiratory alkalosis; (3) salicylate-induced increased permeability of the renal tubules with further loss of potassium; (4) intracellular accumulation of sodium and water; and (5) inhibition of the active transport system, secondary to uncoupling of oxidative phosphorylation. The net result is rapid depletion of potassium stores.⁴

A salicylate-induced decrease in renal blood flow or direct nephrotoxicity may cause acute nonoliguric renal failure. Salicylate-induced secretion of inappropriate antidiuretic hormone may also affect renal function.⁵
Symptoms of Salicylate toxicity

Vomiting can occur 3 to 8 hours after ingestion. Serious dehydration can occur from hyperpnea, vomiting, and hyperthermia. CNS manifestations are usually associated with acidemia. Shortness of breath and altered sensorium are caused by pulmonary and cerebral edema, respectively. Noncardiac pulmonary edema may be more common in children than scattered case reports suggest. Failure to recognize salicylate toxicity as the cause of pulmonary edema increases the likelihood of morbidity and mortality in these patients.

Diagnostic Strategies

A serum salicylate concentration should be measured 6 hours or more after ingestion. A second sample should be obtained 2 hours later. If the second concentration is greater than the first, serial concentrations should be obtained to monitor continued absorption.

Prognosis and treatment of the acutely poisoned patient should be determined by the serum salicylate concentration; the dose of salicylate ingested; and the patient's age, clinical features, and acid-base status. Acid-base status can change quickly, and frequent monitoring of arterial pH is necessary to guide treatment. The Done nomogram should not be used to determine prognosis or treatment.

Salicylate-poisoned patients who require endotracheal intubation are extremely ill, and dialysis is indicated unless the intubation was undertaken because of toxicity of congenerants. Positive-pressure ventilation cannot maintain the respiratory rate required. Hemodynamic instability and worsening acid-base status usually follow intubation. Low pH and bicarbonate levels portend severe disease. The pH begins to drop when the patient is unable to compensate for the acidosis. Lactic acid accumulates, and serum bicarbonate is consumed. When pH is less than 7.4, and both Pco2 and bicarbonate are low, the patient begins to decompensate hemodynamically. In the intubated patient or the acidoic patient with low Pco2 and bicarbonate, hemodialysis should be undertaken.

Differential Considerations

The symptoms of salicylism (hyperthermia, altered mental status or coma, pulmonary edema, and shock) mimic sepsis and the symptoms of many other diseases (Box 147-1). This is especially true with chronic ingestion—serum salicylate concentration is relatively low, and the severity of the poisoning is not recognized. Death is caused by CNS depression and cardiovascular collapse.

Management

Treatment of salicylate toxicity has two main objectives: (1) to correct fluid deficits and acid-base abnormalities and (2) to increase excretion (Box 147-2). Strategies to limit absorption

Clinical Features

A toxic dose of aspirin is 200 to 300 mg/kg, and ingestion of 500 mg/kg is potentially lethal. The initial manifestations of acute salicylate toxicity include tinnitus, impaired hearing, hyperventilation, vomiting, dehydration, and hyperthermia. Salicylate-induced hyperpnea may manifest as increased respiratory depth without commensurate increase in rate. Hyperventilation is more common in adults, who usually have an initial respiratory alkalosis. Young children are predisposed to toxicity due to the metabolic acidosis, which increases tissue and CNS salicylate concentrations. Vomiting can occur 3 to 8 hours after ingestion.

Pulmonary and Cerebral Edema

The exact mechanism by which salicylate increases alveolar capillary membrane permeability is unknown. Theories include inhibition of prostacyclin, changes in platelet-vessel interaction, and neurogenic influences. In adults, the risk factors for salicylate-induced pulmonary edema include age older than 50 years, cigarette smoking, chronic salicylate ingestion, metabolic acidosis, neurologic symptoms, and serum salicylate concentration greater than 40 mg/dL. Risk factors in children include high serum salicylate levels, large anion gap, decreased serum potassium concentration, and low Pco2.

Any alteration in sensorium is evidence of cerebral edema and is a grave prognostic sign. Factors causing cerebral edema are unknown. Patients with cerebral or pulmonary edema require immediate dialysis.

Chronic Ingestion Physiology

Physiologic changes of aging predispose elderly patients to toxicity from chronic therapeutic ingestion. Decreased liver blood flow rates decrease biotransformation of salicylate, and decreased renal function decreases salicylate clearance. Chronic ingestion of aspirin decreases albumin binding, which increases free salicylate. The free salicylate enters the cell, causing significant clinical illness with a relatively low serum salicylate concentration. A patient with chronic salicylate toxicity and a serum concentration of 40 mg/dL may be more ill than a patient with an acute ingestion and serum concentration of 80 mg/dL.

Pediatric salicylism from supratherapeutic dosing may be more serious than acute ingestion. Sweating, fever, and tachycardia caused by salicylism may be attributed to underlying infection. Other sources of salicylate exposure include breast milk, teething gels, and percutaneous absorption of skin ointments, which have high concentrations of methyl salicylate.

Box 147-1 Symptoms of Salicylate Toxicity

| Asymptomatic: Occasional subjective but no objective manifestations |
| Mild: Mild to moderate hyperpnea tinnitis, sometimes with lethargy |
| Moderate: Severe hyperpnea, prominent neurologic disturbances, such as marked lethargy or agitation, but no coma or convulsions |
| Severe: Severe hyperpnea, coma, or semicona, sometimes with convulsions |
TREATMENT OF ACUTE SALICYLATE POISONING

Treat dehydration; maintain urine output at 2–3 mL/kg/hr with 5% dextrose (D$_5$) in lactated Ringer’s solution or normal saline.

Correct potassium depletion.

Alkalize urine.

- Obtain baseline arterial blood gas values.
- If pH is <7.4, administer sodium bicarbonate to obtain pH of 7.4 (50 mL bicarbonate increases serum pH by 0.1 in an adult).
- Infuse intravenous fluids: D$_5$ with 100–150 mEq bicarbonate/L.
- Monitor serum pH; do not cause systemic alkalosis.
- Do not attempt forced diuresis.
- Monitor for dialysis indications: Coma, seizure; Renal, hepatic, or pulmonary failure; Pulmonary edema; Severe acid-base imbalance; Deterioration in condition; Serum salicylate concentration ≥100 mg/dL after acute ingestion; Serum salicylate concentration ≥40 mg/dL after chronic ingestion.

Urinary Alkalization

Because salicylates have a low pH and are renally excreted, alkaline urine traps the salicylate ion and increases excretion. Urinary alkalization is advisable in patients with salicylate levels greater than 35 mg/dL, significant acid-base disturbance, or increasing salicylate levels. A urine pH of 7.5 to 8.0 is necessary to increase excretion. Sodium bicarbonate (1–2 mEq/kg) can be administered over 1 to 2 hours, with subsequent dosage adjustment determined by urinary and serum pH.

Urinary alkalization is difficult to achieve because the excretion of salicylic acid in the urine decreases urinary pH. Additionally, potassium depletion must be corrected to attain an alkaline urine. Alkaline urine should not be produced at the cost of systemic alkalosis. Forced diuresis does not significantly increase salicylate excretion and may potentiate cerebral and pulmonary edema. Salicylate clearance varies in direct proportion to flow rate, but increases exponentially with pH.

Hemodialysis

Hemodialysis is advisable in patients with the following: serum salicylate levels greater than 100 mg/dL in acute intoxication and 50 mg/dL in chronic salicylate poisoning; altered mental status; endotracheal intubation other than for coagstents; coma; renal or hepatic failure; pulmonary edema; severe acid-base imbalance; rapidly rising serum salicylate level; and failure to respond to more conservative treatment. Exchange transfusion can be considered in young infants or unusual cases of congenital salicylism.

Pregnancy

Greater salicylate concentration on the fetal side of the placenta and relative fetal acidemia contribute to fetal distress from maternal salicylate poisoning. Salicylate poisoning during pregnancy is associated with fetal demise, and delivery of the distressed fetus should be considered if the fetus is viable.

Disposition

In patients with acute intoxication, hospital admission is required for pulmonary edema, CNS symptoms (other than tinnitus), seizures, acidosis, electrolyte disorders, dehydration, renal insufficiency, or increasing serum levels. In patients with chronic intoxication, remarkably low serum salicylate concentrations may accompany severe salicylism. Any indication of infant salicylism requires hospital admission. The mortality rate for chronic salicylate intoxication is 25%, compared with a mortality rate of 1% following acute salicylate intoxication.

In patients with acute ingestion, a second serum salicylate concentration measurement is essential to determine whether the peak serum concentration has been attained. Patients should not be discharged unless the serum concentrations are decreasing. As in any case of intentional overdose, psychiatric evaluation is essential.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Perspective

The nonsteroidal anti-inflammatory drugs (NSAIDs) are a heterogeneous group of agents with variable analgesic, anti-inflammatory, and antipyretic activities. They are usually classified according to chemical structure, although classification based on cyclooxygenase (COX) selectivity may be more
clinically relevant. NSAIDs are widely prescribed for a variety of conditions. Ibuprofen and naproxen are available in over-the-counter and prescription strengths.

Principles of Disease

Physiology

The therapeutic anti-inflammatory effect of the NSAIDs is achieved by inhibition of COX and consequent blockade of prostaglandin production. Of the two discrete COX isoenzymes, COX-1, the constitutive enzyme, is concentrated in platelets, vascular endothelial cells, gastric mucosal cells, and renal collecting tubules. It is a physiologic maintenance enzyme, producing the prostaglandins critical for the autocrine-paracrine responses to circulating hormones and the maintenance of normal renal function, gastric mucosal integrity, and hemostasis. COX-2, the inducible enzyme, is expressed only in response to certain inflammatory stimuli. The benefits of NSAIDs are thus believed to result from COX-2 inhibition, whereas the principal gastrointestinal and renal adverse effects are attributed to inhibition of COX-1.

Traditional NSAIDs are nonselective and inhibit both COX-1 and COX-2. Newer, specific COX-2 inhibitors (e.g., celecoxib, rofecoxib, parecoxib, meloxicam) have fewer side effects than traditional NSAIDs while maintaining analgesic and anti-inflammatory efficacy. However, COX-2 inhibitors permit unopposed thromboxane A2 production by platelets, thereby potentiating platelet aggregation, thrombosis, and vasoconstriction.16 Therapeutic use of rofecoxib, particularly at higher doses, is associated with increased risk of myocardial infarction and stroke and has subsequently been withdrawn from the market.17,18

Pharmacokinetics

The NSAIDs are almost completely absorbed from the upper small intestine after oral administration. The presence of food may alter the site and timing of drug uptake. As weak organic acids (pKa, 4–5), NSAIDs are largely nonionized in the stomach and readily diffuse across the bipolar layer lipid membrane of gastric-lining cells. Once intracellular, the drug can become ionized again at the relatively high pH of normal cytoplasm and become trapped within the mucosal cell. This relatively high local concentration of drug contributes to the frequent gastrointestinal symptoms associated with NSAIDs.

The NSAIDs are highly bound to plasma proteins, mainly albumin, and therefore have small volumes of distribution (0.10–0.17 L/kg). They are eliminated by hepatic biotransformation, principally oxidation and glucuronidation, with the metabolites being excreted in the urine. Metabolites are inactive, except for those of sulindac, nabumetone (inactive parent drugs metabolized to active agent in vivo), and phenylbutazone. Plasma half-lives are short (1–4 hr), except for naproxen (12–15 hr), oxaprozin (25–50 hr), piroxicam (45 hr), and phenylbutazone (50–100 hr). Elimination half-lives are not substantially prolonged in overdose.19

Clinical Features

Most NSAID overdoses, even with large amounts, are asymptomatic or cause only minor CNS or gastrointestinal disturbances. Experience with overdose of the newer COX-2 inhibitors is limited, but significant toxicity is not reported. Of all isolated celecoxib exposures reported to the Texas poison control centers over a 5-year period, no more than minor effects were reported and then in only 12% of cases.20

Ibuprofen is the most common NSAID ingested in overdose and is representative of the propionic acid derivatives. Despite rare case reports of coma, seizure, hypotension, hyperthermia, upper gastrointestinal tract bleeding, acute renal failure, and metabolic acidosis, the vast majority of ibuprofen overdoses follow a benign, rapidly self-limiting course. About 50% of adults and 7% of children develop symptoms. Symptomatic overdose occurs only after ingestion of at least 100 mg/kg, and all those who develop symptoms do so within 4 hours of ingestion. Life-threatening symptoms or signs are rare, and most toxicity is a mild gastrointestinal or CNS disturbance that resolves in 24 hours.21-25 Less common clinical effects include mild metabolic acidosis, muscle fasciculations, mydriasis, chills, diaphoresis, hyperventilation, mildly elevated systolic blood pressure, asymptomatic bradycardia, hypotension, dyspnea, tinnitus, and rash.

Reversible renal dysfunction is seen only after massive acute overdose and in association with a period of relative hypovolemia with hypotension.21,26 It usually responds to supportive measures, although deaths have been reported.27 Serum ibuprofen concentrations do not predict toxicity.21

Overdose with mefenamic acid, a fenamate, is associated with a relatively high incidence of seizures, which occur 2 to 7 hours after ingestion.28 Rapid recovery is the rule with supportive care and intravenous benzodiazepines. Serum mefenamic acid concentrations correlate with seizures but do not aid in acute management.

Phenylbutazone, a pyrazolone, is now rarely used because of its association with aplastic anemia and agranulocytosis. Although rare, phenylbutazone overdose is much more severe than overdose with other NSAIDs.29 Mild poisoning consists of nausea, abdominal pain, and drowsiness. Severely poisoned patients have early onset of abdominal pain, nausea, vomiting, hematemesis, diarrhea, restlessness, dizziness, coma, convulsions, hyperpyrexia, electrolyte disturbances, hyperventilation, alkalosis or acidosis, respiratory arrest, hypotension, cyanosis, edema, electrocardiographic abnormalities, or cardiac arrest. Late sequelae of severe poisoning (2–7 days) include renal, hepatic, and hematologic dysfunction. The clinical course is prolonged compared with other NSAID poisoning, reflecting the prolonged elimination half-lives of phenylbutazone and its principal metabolite, oxyphenbutazone.

Diagnostic Strategies

The diagnosis and assessment of severity and risk are based on history and clinical features. Plasma NSAID concentrations are not useful, but screening for acetaminophen should be done. Serum electrolyte levels, renal and hepatic function tests, serum salicylate level, urinalysis, and chest radiograph should be undertaken as indicated by specific clinical concerns.

Management

The management of NSAID overdose is supportive, and there is no specific antidote. Pyrazolone and fenamate overdoses are associated with significantly higher morbidity and should be managed more aggressively.

Children with ingestions of less than 100 mg/kg of ibuprofen do not require medical evaluation. Those who ingest more than 300 mg/kg should be evaluated. With ingestion of 100 to 300 mg/kg, children need treatment only if symptoms develop.

All patients with pyrazolone and fenamate ingestions should be evaluated in the emergency department. For other agents, emergency department evaluation is indicated if the amount
ingested is greater than five times the maximum daily therapeutic dose, the patient is symptomatic, or a suicide attempt is suggested.

There is no evidence supporting the use of gastric emptying or AC in cases of NSAID overdose, although AC has historically been used and it is not recommended. All patients with nontrivial overdoses should be observed until 4 hours post-ingestion and until symptoms are noted to be mild or improving. Hypotension, if it occurs, is managed with intravenous crystalloid solution. Although rarely indicated, and not subjected to study, extracorporeal membrane oxygenation has been successfully used to manage refractory hypotension following massive ibuprofen overdose.30

Because of high protein binding and rapid metabolism, urinary alkalinization, hemodialysis, or hemoperfusion is not clinically useful. Multidose AC reduces the elimination half-life of phenylbutazone by 30% and may be of benefit in cases of severe intoxication.31

Disposition

Patients who are mildly symptomatic or asymptomatic for more than 4 hours after an NSAID overdose do not require further medical care, other than possible psychiatric evaluation. Patients who have ingested a pyrazolone or fenamate may require longer observation for possible seizures. Admission to the ED observation unit until 8 hours after ingestion may be advisable, but studies have not been done to verify this. Patients who develop significant symptoms or signs of toxicity from the NSAID or a co-ingestant and who require supportive care should be admitted to the hospital or an emergency department observation unit for ongoing medical treatment. Patients with only gastrointestinal or neurologic symptoms may be observed in the emergency department until asymptomatic or improving. All patients for whom the ingestion represented a suicidal gesture need to undergo psychiatric assessment before hospital discharge.

CHAPTER 148  Anticholinergics

Larissa I. Velez and Sing-Yi Feng

Anticholinergic agents are divided into three main groups: (1) antimuscarinics, affecting the muscarinic acetylcholine (ACh) receptors; (2) neuromuscular blockers, blocking nicotinic ACh receptors; and (3) ganglionic blockers, affecting ACh sympathetic and parasympathetic nicotinic ganglia (Fig. 148-1). This chapter refers only to antimuscarinic agents, and the terms anticholinergic and antimuscarinic will be used interchangeably.

The prototypical anticholinergic agents are the naturally occurring belladonna alkaloids—atropine, scopolamine (t-hyoscine), and hyoscyamine—found in many plant members of the Solanaceae family. Atropine is the major alkaloid of Atropa belladonna, an important pharmaceutical source of that drug, Datura stramonium, or Jimson weed, contains scopolamine, grows in almost all climates, and is often involved in plant-related belladonna poisoning. Atropine and atropine-like drugs inhibit muscarinic ACh receptors both centrally and peripherally at the end-organ sites of the parasympathetic nervous system (see Fig. 148-1). Although the term anticholinergic is commonly used, the most appropriate term to describe the pharmacologic action of these drugs is antimuscarinic. These drugs do not block the effects of ACh on nicotinic receptors in the ganglia or at the neuromuscular junction, with the exception of the synthetic quaternary amines. Muscarinic receptors affect smooth muscle function in the eye, intestinal tract, and urinary bladder. They also regulate sweat, salivary, and mucosal gland activity. Cardiac cholinergic receptors associated with vagal nerve fibers affect heart rate and conduction through the atrioventricular

PERSPECTIVE

Anticholinergic agents are divided into three main groups: (1) antimuscarinics, affecting the muscarinic acetylcholine (ACh) receptors; (2) neuromuscular blockers, blocking nicotinic ACh receptors; and (3) ganglionic blockers, affecting ACh sympathetic and parasympathetic nicotinic ganglia (Fig. 148-1). This chapter refers only to antimuscarinic agents, and the terms anticholinergic and antimuscarinic will be used interchangeably.

The prototypical anticholinergic agents are the naturally occurring belladonna alkaloids—tropine, scopolamine (t-hyoscine), and hyoscyamine—found in many plant members of the Solanaceae family. Atropine is the major alkaloid of Atropa belladonna, an important pharmaceutical source of that drug, Datura stramonium, or Jimson weed, contains scopolamine, grows in almost all climates, and is often involved in plant-related belladonna poisoning. Atropine and atropine-like drugs inhibit muscarinic ACh receptors both centrally and peripherally at the end-organ sites of the parasympathetic nervous system (see Fig. 148-1). Although the term anticholinergic is commonly used, the most appropriate term to describe the pharmacologic action of these drugs is antimuscarinic. These drugs do not block the effects of ACh on nicotinic receptors in the ganglia or at the neuromuscular junction, with the exception of the synthetic quaternary amines. Muscarinic receptors affect smooth muscle function in the eye, intestinal tract, and urinary bladder. They also regulate sweat, salivary, and mucosal gland activity. Cardiac cholinergic receptors associated with vagal nerve fibers affect heart rate and conduction through the atrioventricular
node. Muscarinic receptors in the CNS appear to be involved in new information storage, general perceptive and cognitive functions, and motor coordination.13-16

Generalized inhibition of muscarinic receptors by atropine results in tachycardia, pupillary dilation, loss of accommodation, inability to sweat, drying of mucosal surfaces, gastrointestinal paralysis, and urinary retention. In the CNS, muscarinic inhibition causes stimulation, seizures, coma, choreoathetosis, memory impairment, and perceptual and cognitive dysfunction.13-19 The mnemonic “hot as a hare, red as a beet, blind as a bat, dry as a bone, mad as a hatter” aptly characterizes the more florid manifestations of the antimuscarinic syndrome. With increasing doses, CNS depression follows the initial stimulation. However, in adults, the CNS depression can predominate without CNS stimulation.20 Various end organs manifest different but predictable sensitivities to antimuscarinic drugs. Salivation, bronchial secretions and sweating are suppressed first, followed by the onset of mydriasis and tachycardia. The least sensitive organs to antimuscarinic drugs are the bladder and the gastrointestinal tract.

Anticholinergics are generally rapidly absorbed and widely distributed throughout the body. Poisoning has been reported after ingestion, smoking, and topical absorption. However, with plant and seed ingestions or after an overdose, the onset of symptoms can be delayed.21 Prolonged anticholinergic toxicity has also been reported, which may indicate slowed

focality on neurologic examination, physical signs of systemic infection, hepatic failure, or thyroid disease suggest alternative diagnoses. The demonstration of hypoglycemia, hypoxia, uremia, or calcium abnormalities also suggests a nontoxic diagnosis.

Except for sinus tachycardia, electrocardiographic abnormalities from a pure anticholinergic overdose are unusual and should suggest a cardiotoxic agent with antimuscarnic side effects, such as a tricyclic antidepressant, carbamazepine, or a phenothiazine. (In the presence of hyperkalemia due to rhabdomyolysis, peaked T waves can be observed.)

**CLINICAL PRESENTATION**

The diagnosis of acute anticholinergic poisoning is suggested by the characteristic anticholinergic toxidrome. Mydriasis, dry mucous membranes, the absence of axillary sweat, flushed skin, fever, tachycardia, decreased or absent bowel sounds, and bladder distention from urinary retention constitute peripheral evidence of muscarinic blockade. The patient is often alert and may be silly, agitated, violent, or incoherent. Visual hallucinations are common. Central motor effects may manifest as myoclonus or choreoathetoid movements. Children are more sensitive to the CNS stimulant effects than adults and are more likely to have seizures, typically preceded by signs of CNS irritability or depression. Massive ingestions are associated with coma and cardiovascular collapse.

The agitated patient with anticholinergic overdose may have a greatly elevated temperature due to both increased motor activity and impaired heat exchange. In such cases, death secondary to hyperthermia supersedes the morbidity of the anticholinergic drug itself. The hyperthermic patient may develop hepatic necrosis, rhabdomyolysis with myoglobinuric renal failure, cerebral edema, and disseminated intravascular coagulation.

Patients with chronic anticholinergic poisoning may be difficult to diagnose. They develop organic mental symptoms that may be incorrectly attributed to dementia or underlying psychiatric illness. Significant peripheral anticholinergic signs are typically absent. Two likely settings for chronic anticholinergic toxicity are (1) the elderly patient taking anticholinergic drugs for parkinsonism or other chronic diseases and (2) the psychiatric patient receiving neuroleptic therapy and started on another anticholinergic drug. Resolution of behavioral or cognitive symptoms after withdrawal of the offending drug confirms the diagnosis.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis of the comatose, psychotic, delirious, or febrile patient is extensive, and serious alternative diagnoses should be considered and excluded. Diagnoses to consider include toxicity and withdrawal from a variety of drugs, metabolic disorders, CNS infections, and other neurologic pathologies. The physical examination findings can be helpful. Patients with excessive sympathetic stimulation secondary to cocaine or amphetamine poisoning exhibit fever, tachycardia, and dilated pupils. Importantly, the finding of diaphoresis helps distinguish patients with sympathetic overload from those with anticholinergic effects; however, this finding can be absent in severely dehydrated patients. Marked nystagmus, diaphoresis, small pupils, and extreme agitation suggest phenylcyclidine poisoning. Lithium or monoamine oxidase inhibitor toxicity should also be considered. These patients usually have tremors and significant hyper-reflexia or clonus, which are not characteristic of anticholinergic poisoning. Patients with serotonin syndrome often present with agitation. These patients are often diaphoretic and have a tremor that is more prominent in the lower extremities. Neuroleptic malignant syndrome and malignant hyperthermia can also manifest similarly, but these patients display rigidity as a prominent physical examination feature.

The nontoxicologic differential diagnosis of acute agitated delirium should consider metabolic, endocrine, infectious, neurologic, and neurosurgical emergencies. Nuchal rigidity or gastrointestinal absorption of the ingested drug or residual drug in the gastrointestinal tract.

**DIAGNOSTIC STRATEGIES**

Mildly symptomatic patients with well-established histories and consistent symptoms do not benefit from routine laboratory testing. In the seriously poisoned patient, laboratory investigation should include measurement of serum electrolytes, renal function, creatine phosphokinase, and glucose. Arterial blood gas measurements document disorders of oxygenation and ventilation and allow early detection of metabolic acidosis. Capillary blood glucose and oxygen saturation measurements are important first steps in the assessment of any patient with altered mental status. Thiamine should be administered to malnourished patients. An electrocardiogram should also be performed early, since certain anticholinergic medications such as tricyclic antidepressants and diphenhydramine can block sodium channels, causing QRS widening.

Broad, nonspecific toxicologic screening is rarely useful in the acute setting, although it may retrospectively confirm a diagnosis in a seriously ill patient. However, patients with significant infectious or neurosurgical problems often have evidence of an incidental toxin. Therefore, a positive toxicology screen should not distract the physician from ruling out a more serious diagnosis.

In any case of intentional ingestion, serum acetaminophen levels should be obtained to exclude this common coingestant, especially because many over-the-counter products contain acetaminophen along with an antihistamine that causes the anticholinergic symptoms.

Computed tomography of the brain and a lumbar puncture exclude neurologic and neurosurgical emergencies in the patient who deteriorates, who fails to improve, or for whom the history or examination suggests an alternative diagnosis.

**MANAGEMENT**

In the emergency department, many patients with anticholinergic poisoning have no clear history of exposure. The patient is often unable to provide a history due to the delirium. Therefore, the diagnosis is often suggested solely on the basis of the physical examination fitting the muscarinic/anticholinergic toxidrome (Box 148-3). The general treatment of these poisoned patients proceeds with consideration of the broader differential diagnosis of the acutely agitated, febrile, or comatose patient.

**Agitation**

The need for titrated sedation with a benzodiazepine, cooling, and hydration takes precedence over specific toxicologic concerns in these critically ill patients. Physical restraint alone is detrimental and is used only briefly to permit pharmacologic intervention. Agitation should be controlled by titrating intravenous benzodiazepines to sedation. Benzodiazepines are preferred over phenothiazines and butyrophenones because exacerbation or induction of hypotension is unlikely, the
Seizures

Seizures should be treated with intravenous benzodiazepines. In the absence of an intravenous line, the intramuscular route can be effectively used for lorazepam or midazolam. Phenytoin is not useful in the management of most toxin-induced seizures. Status epilepticus is rare in anticholinergic poisoning and should suggest an alternative diagnosis.

Drug Removal

Decontamination of the patient with documented or strongly suggested anticholinergic poisoning must be individualized, based on time since exposure, type of anticholinergic agent involved, route of exposure, probable amount ingested, and severity of the clinical condition. Early gastric emptying (within 1 hour) may be considered for large ingestions, when an asymptomatic patient presents almost immediately after ingestion, but this rarely occurs. There is no evidence that gastric lavage improves outcome, and it is hazardous in agitated patients.

Activated charcoal has been shown to be efficacious in adsorbing diphenhydramine, tricyclic antidepressants, and phenothiazines. However, there is no evidence that it improves outcome, and it should not be routinely used to decontaminate poisoned patients. Overall, there is insufficient evidence to support the use of either gastric emptying or activated charcoal (single or multiple doses) in patients with anticholinergic poisoning.

Physostigmine

Physostigmine is a naturally occurring acetylcholinesterase inhibitor, similar to neostigmine, pyridostigmine, and edrophonium. These agents block the degradation of ACh, which then accumulates in the synaptic space and overcomes the effects of ACh receptor blockade. Physostigmine, as a tertiary amine, is the only agent that can cross the blood-brain barrier and overcomes both central and peripheral muscarinic blockade.

The role of physostigmine in the management of anticholinergic overdoses has been controversial. In the absence of anticholinergic blockade, physostigmine itself has significant toxicity. It can precipitate cholinergic excess, causing seizures, muscle weakness, bradycardia, bronchoconstriction, laryngospasm, salivation, bronchorrhea, vomiting, and diarrhea. Even in documented cases of anticholinergic toxicity, seizures have been reported after the rapid administration of physostigmine. Asystole has occurred after the administration of physostigmine for tricyclic antidepressant overdose, so a conduction delay (QRS > 0.10 sec) or suggestion of tricyclic antidepressant ingestion is generally considered a contraindication to physostigmine administration.

A retrospective study showed that physostigmine reverses delirium in 87% and agitation in 96% of patients with anticholinergic overdose. Benzodiazepines controlled agitation in 24% of patients but did not reverse delirium. This study excluded patients with QRS widening unrelated to a bundle branch block. Physostigmine can be used diagnostically in patients with obvious anticholinergic signs or suggested anticholinergic poisoning. Reversal of coma or severe agitation and normalization of mental status may avoid the need for further diagnostic evaluation. Physostigmine should not be used in patients with suspected tricyclic antidepressant ingestion or as an empiric “coma” therapy.

To minimize toxicity, physostigmine should be infused over 5 minutes in an initial dose of 1 to 2 mg for adults and

possibility of seizures is decreased, and there are no added anticholinergic effects. Pharmacologic restraints in the agitated patient prevent self-injury, severe hyperthermia, and the development of myoglobinuric renal failure from muscle injury. Control of the agitation also allows for a more thorough physical examination and for diagnostic procedures to take place. Intubation is generally not indicated as the sole treatment for agitation.

**Hyperthermia**

Deaths of agitated patients could be associated with unrecognized hyperthermia. The patient's core temperature should be measured with a flexible rectal probe. Aggressive temperature reduction with ice water or evaporative cooling with mist and fans should be the first priority in the severely hyperthermic patient. Benzodiazepines should be used to prevent shivering, which can hinder adequate cooling. The use of dantrolene sodium, a drug that decreases rigidity caused by abnormal calcium fluxes in muscle tissue in malignant hyperthermia, has no role in the treatment of hyperthermic patients who do not have muscle rigidity. Antipyretic agents and simple cooling blankets are ineffective.
0.02 mg/kg (max 0.5 mg) for children to control severe anticholinergic manifestations. This dose can be repeated in 10 to 15 minutes until a clinical response is obtained. The onset of action is within minutes of the drug’s administration. Atropine should be available at the bedside, and the physostigmine infusion immediately stopped if signs of cholinergic excess develop. Since physostigmine has a relatively short duration of action of 1 hour, repeated doses may be required if clinical relapse occurs.48

■ DISPOSITION

Most patients with anticholinergic overdoses recover rapidly with sedation, temperature control, hydration, and observation. Patients who are alert, or have symptoms and vital signs that normalize during observation in the emergency department, do not require hospital admission. Patients with hyperthermia, agitation, coma, or seizures should be admitted to an intensive care unit.

The onset of symptoms after most anticholinergic ingestions is rapid; 4 hours of observation is adequate to exclude significant toxicity in an asymptomatic patient. Patients who have ingested Datura stramonium seeds should be observed for 8 hours because of delayed absorption.49 Predischarge measures include psychiatric assessment, exclusion of other toxins including documentation of a nontoxic acetaminophen level, and assessment of a child’s home situation.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Antidepressants consist of a wide variety of drugs, including cyclic antidepressants (CAs), selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), and miscellaneous agents (Table 149-1). Antidepressants can be classified based on structure or major mechanism of action. Antidepressants account for only 4% of poisonings; however, they are involved in 23% of poisoning deaths and are the third most common cause of death from poisoning. Overdoses with SSRIs result in lower morbidity and mortality than overdoses with tricyclic antidepressants (TCAs) and MAOIs. Toxicity with miscellaneous antidepressants occurs less frequently than with TCAs and usually involves co-ingestants.

### CYCLIC ANTIDEPRESSANTS

#### Principles of Disease

TCAs and the tetracyclic antidepressant maprotiline have similar properties and are called CAs. The CAs are well absorbed from the gastrointestinal tract and reach peak plasma concentrations in 2 to 4 hours after therapeutic doses are reached. Absorption is prolonged in overdose because the anticholinergic effect delays gastrointestinal motility and absorption. These pharmacokinetic data are compatible with the recommended 6-hour observation period in management of CA overdose (Fig. 149-1). CAs are highly lipophilic, are extensively bound to plasma proteins, and have large volumes of distribution. CAs are metabolized predominantly by the liver.

TCAs and their active metabolites have two basic structures: tertiary amines and secondary amines. All tertiary-amine TCAs are metabolized to secondary amines that are active. Amitriptyline forms nortriptyline, and imipramine forms desipramine. Amoxapine, a secondary amine, is metabolized to active intermediates by hepatic hydroxylation. Hydroxylation of other secondary-amine TCAs results in inactive metabolites. The parent compounds and the active metabolites may undergo enterohepatic circulation.

Seven major pharmacodynamic effects of CAs result in characteristic signs and symptoms of toxicity and are manifested mainly in the cardiovascular and nervous systems (Box 149-1). Phase 0 myocardial depolarization is prolonged when sodium conductance is blocked through fast sodium channels. This results in decreased conduction with a prolonged QRS complex (>100 msec) and negative inotropic effects. Impaired excitation-contraction coupling within myocardial cells and diminished release of calcium from sarcoplasmic calcium stores decrease contractility. Alpha₁-adrenoreceptor blockade can result in vasodilation in all vascular beds, causing hypotension from decreased preload and afterload. Alpha₁-blockade can decrease systemic vascular resistance, widen pulse pressure, and decrease pupil size.

Serotonin and norepinephrine reuptake inhibition within the central nervous system (CNS) predisposes to agitated delirium and seizures. Peripheral inhibition of catecholamine reuptake results in increased circulating catecholamines and initial hypertension. Eventual metabolism of peripheral catecholamines by catechol-O-methyltransferase results in late hypotension and bradycardia.

Anticholinergic and antihistamine effects are associated with peripheral autonomic nervous system antimuscarinic effects (Box 149-2) and CNS effects of delirium, seizures, sedation, and coma (Box 149-3). Potassium efflux blockade prolongs phase 3 of the myocardial action potential—repolarization—resulting in an increased duration of the QT interval. This increases the risk for developing torsades de pointes. CAs promote CNS excitation and seizures because of their indirect inhibition of γ-aminobutyric acid (GABA), the primary cerebral inhibitory neurotransmitter. CAs bind to the picrotoxin site of the GABAₐ receptor-chloride ionophore complex.

#### Clinical Features

CA poisoning initially manifests with anticholinergic symptoms, including sinus tachycardia and early hypertension (see Chapter 148). Severe poisoning is characterized by subsequent convulsions, coma, and cardiovascular collapse. CA toxicity should be considered in all patients with a decreased level of consciousness and prolonged QRS complex. Mental status changes do not predict the occurrence of seizures, and 23% of patients are awake and alert immediately before a seizure. Hypotension caused by CA poisoning can occur with or without QRS prolongation (>100 msec). Hypotension can result from myocardial depression or peripheral vasodilation. Catastrophic cardiovascular collapse closely follows seizures in 13% of patients with CA-induced seizures. Cardiovascular collapse is attributed to lactic acidosis, which impairs myocardial sodium conduction.

Patients can deteriorate rapidly, and even patients with trivial signs of poisoning on presentation can have a 50% mortality rate. Because of rapid deterioration, death rates of 44%

*With disinhibition of serotonin and norepinephrine neurotransmission (i.e., increased neurotransmission).
DA, dopamine; 5-HT, serotonin; NE, norepinephrine.

have been reported for patients en route to the hospital, many of whom were initially awake and alert with normal sinus rhythm. Most serious complications develop within 30 to 60 minutes of presentation, usually while in the emergency department.

CAs also can cause cardiogenic or noncardiogenic pulmonary edema. Acute myocardial infarction is rare in the setting of CA toxicity. Amoxapine has fewer cardiac effects but a greater incidence of seizures. The tetracyclic, maprotiline, has more cardiac and CNS effects than TCAs.

Diagnostic Strategies
A history of CA overdose is the most helpful diagnostic indicator. A dose greater than 10 mg/kg or 1000 mg in an adult should be considered life-threatening. Patients who have an anticholinergic toxidrome, decreased level of consciousness, QRS prolongation (>100 msec), or rightward deviation of the terminal 40-msec QRS axis (R wave in aVR > 3 mm or R/SaVR ratio of <0.7) should be considered to have CA poisoning until
Proven otherwise (Fig. 149-2). With QRS prolongation greater than 100 msec in the limb leads, 30% of patients experience seizures; for prolongation greater than 160 msec, 50% develop dysrhythmias. CAs can induce an electrocardiogram (ECG) pattern consistent with the Brugada’s syndrome, a genetic disorder resulting in sodium channel dysfunction. A right bundle branch block and ST segment elevation in the right precordial leads (V1 through V3) are seen. CA toxicity is not fully excluded with normal ECG findings.

Quantitative serum toxicology tests for CAs are not usually available in a timely fashion and do not predict adequately the degree of toxicity. Qualitative laboratory tests may document exposure. Neither serum toxicology tests nor laboratory tests are useful for clinical decision-making. Diagnosis, treatment, and disposition should be based on a clinical basis and with ECG and cardiac monitoring.

**Differential Considerations**

The differential diagnosis of CA poisoning is extensive and includes intoxications by anticholinergic, psychiatric, and cardiac medications, especially type I antidysrhythmics. Many conditions cause sinus tachycardia and hypotension with a wide pulse pressure; however, QRS widening, seizures, or coma suggests CA poisoning.

**Management**

Treatment begins with assessment of airway and breathing. Endotracheal intubation should be performed if the patient is exhibiting a markedly decreased level of consciousness or if the level of consciousness is rapidly deteriorating. Respiratory depression, with attendant hypoxia and hypercarbia, significantly increases morbidity and mortality from CA poisoning. Patients with overdoses severe enough to require admission to the intensive care unit (ICU) have a high incidence of airway and breathing complications, with aspiration pneumonitis reported in 13 to 18% of patients. The initial benign appearance of the patient’s presentation may be deceptive; rapid deterioration with cardiac dysrhythmias, generalized seizures, and death can occur despite appropriate management.

Ventilatory support to avoid respiratory acidosis is crucial because acidosis inhibits conductance through fast sodium channels. Any patient with a significant CA overdose should have continuous pulse oximetry. Arterial blood gas determination or capnography may be helpful when ventilatory function is questionable despite normal oxygen saturations on pulse oximetry. Patients with low minute volumes, hypoxia, and acidosis can appear clinically to be ventilating adequately.

Gastric lavage and administration of activated charcoal within 60 minutes from time of significant ingestion is theoretically appealing, and despite the general lack of evidence for efficacy, the toxicity of these drugs is high and any decrease in the absorption may be helpful. If the patient is thought to have ingested sufficient CA to prompt gastric lavage, this should be preceded by intubation for airway protection, since the risk of deterioration is high. The use of physostigmine is not recommended. Seizures, cardiac arrest, and death have occurred when physostigmine has been used in CA overdose.

Hypertension is usually mild and transient and requires no treatment (Table 149-2). Treatment of hypotension begins with isotonic crystalloids. If the QRS is greater than 100 msec, and the patient is symptomatic, with hypotension or a dysrhythmia, or if the patient is acidemic, intravenous (IV) sodium bicarbonate (NaHCO3) also should be administered. NaHCO3 produces an alkaline pH and provides a sodium load and hypertonicity that increase sodium conductance through myocardial fast sodium channels. Hyperventilation and hypertonic sodium chloride also enhance sodium conduction.

Hypertonic sodium chloride has been used for treating hypotension with QRS widening caused by CA-induced cardiotoxicity unresponsive to standard therapies. Serum alkalization is clinically effective in decreasing CA-induced intraventricular conduction delays. The major effect of increasing pH seems to be increased sodium conductance through myocardial sodium channels rather than the increase in plasma protein binding. NaHCO3 is administered by IV boluses of 1 to 2 mEq/kg until the QRS narrows or until serum pH increases to 7.50 to 7.55. After obtaining the desired endpoint with IV NaHCO3 boluses, a continuous infusion can be maintained by adding three ampules of 8.4% NaHCO3 (50 mEq/ampule, 100 mOsm/ampule) to 1 L of 5% dextrose in water. The initial IV infusion is started at a usual maintenance rate for IV fluids, based on the patient’s weight. This initial NaHCO3 infusion rate often must be maintained for at least 4 to 6 hours before the rate can be decreased. For a hypertonic continuous IV solution, four ampules of 8.4% NaHCO3 can be added to 1 L of 5% dextrose in water. This infusion is occasionally necessary for refractory hypotension with a prolonged QRS or refractory ventricular dysrhythmias.

Excess NaHCO3 and saline can worsen heart failure and should be avoided. Excessive alkalemia from combined use of hyperventilation and NaHCO3 can result in complications, including death. Repeat boluses and continuous IV infusion should be guided by serial measurements of arterial pH and QRS duration. When symptoms are refractory, hypertonic
sodium chloride boluses can be used to treat hypotension and a wide QRS interval with ventricular ectopy. If hypotension does not resolve, norepinephrine or dopamine is recommended. High-dose dopamine (20–30 µg/kg/min) and norepinephrine (0.1–1 µg/kg/min) may be necessary for the direct alpha1-agonist effect. For inotropic support alone, dobutamine is controversial. Vasopressin has been used to treat refractory hypotension following amitriptyline poisoning; and intralipid infusion has been used in an animal model to successfully treat hypotension due the fat-soluble drug clomipramine.

Sinus tachycardia is usually well tolerated and does not require specific therapy. Beta-receptor antagonists and physostigmine should not be used. Wide-complex tachycardia is
not always ventricular tachycardia and can represent sinus tachycardia with aberrant conduction; however, treatment in either case is IV NaHCO3. 

Phenytin has been shown to increase the frequency and duration of episodes of ventricular tachycardia and is not recommended as an antidysrhythmic agent. 

Type IA antidysrhythmics (quinidine, disopyramide, procainamide) and type IC antidysrhythmics (flecainide, moricizine, propafenone) are contraindicated because they also inhibit fast sodium channels. A transvenous pacemaker and overdrive pacing can be used for CA-associated polymorphic ventricular tachycardia (torsades de pointes) that is not responsive to magnesium. CA poisoning can result in increased threshold requirements for ventricular pacing and decreased electric cardioversion and defibrillation effectiveness. Bradydysrhythmias are rare and late in CA overdose.

QT prolongation, PR prolongation, and rightward terminal 40-msec QRS axis deviation do not mandate specific therapy. 

Treatment with NaHCO3, hypertonic sodium chloride, and hyperventilation does not completely correct QT prolongation, which involves not only sodium channel blockade, but also protracted repolarization from potassium efflux blockade.

Treatment of neurologic complications of CA poisoning includes early intubation with mechanical ventilation for coma (Table 149-3). Benzodiazepines should be used for agitation because they do not have the anticholinergic or cardiac conduction effects of some antipsychotic medications. Status epilepticus or prolonged seizures account for 20 to 30% of the seizures caused by CAs. 

Seizures refractory to other benzodiazepines have terminated with IV midazolam boluses of 2.5 to 10 mg and continuous IV infusions. 

If benzodiazepines fail to terminate prolonged or repetitive seizures, phenobarbital may be administered in a loading dose of 20 mg/kg, given at a rate of up to 50 mg/min in adults or up to 1 mg/kg/min in children. Propofol is also used to treat refractory seizures successfully. A loading dose of 2.5 mg/kg is followed by continuous infusion of 25 to 200 µg/kg/min. 

Phenytin may cause more and longer episodes of ventricular tachycardia and is unlikely to be effective for seizures. If maximal doses of benzodiazepines, phenobarbital, or propofol are ineffective, neuromuscular blockade and general anesthesia with continuous electroencephalogram monitoring are recommended to prevent rhabdomyolysis and hyperthermia caused by excessive muscle activity.
Flumazenil is contraindicated, even if benzodiazepines are known coingestants.\(^{35,36}\) Flumazenil counteracts the anticonvulsant activity of the co-ingested benzodiazepines. Seizures, ventricular tachycardia, and ventricular fibrillation can occur when flumazenil is used in mixed benzodiazepine-CA overdoses.\(^{36}\)

Life-threatening hyperthermia (rectal temperature > 40°C) is best treated with control of seizures and neuromuscular blockade. A nondepolarizing neuromuscular blocker (e.g., rocuronium) is recommended if rhabdomyolysis and hyperkalemia with ECG changes are present. Evaporative cooling should be used until core temperature reaches 38.5°C. Forced diuresis, hemodialysis, and hemoperfusion are not helpful because CAs have large volumes of distribution, are highly bound to plasma proteins, and are minimally eliminated by the kidneys.

**Disposition**

Patients with known or possible CA overdoses require observation with continuous cardiac monitoring and pulse oximetry. After 6 hours of observation, patients may be discharged for psychiatric evaluation if they do not develop (1) ventilatory insufficiency, (2) desaturation on pulse oximetry, (3) QRS greater than 100 msec, (4) sinus tachycardia greater than 120 beats/min, (5) dysrhythmias, (6) hypotension, (7) decreased level of consciousness, (8) seizures, or (9) abnormal or inactive bowel sounds. Patients who exhibit any of these findings should be admitted to an ICU (see Fig. 149-1).\(^{9,10}\)

**Clinical Features**

**Overdose**

The signs, symptoms, and morbidity and mortality rates for SSRI poisoning are much less than for CA poisoning. The organ systems most affected by excessive serotonin are the gastrointestinal tract, cardiovascular system, and CNS (Table 149-4). Overdose can cause sedation, agitation, tremor, hyper-reflexia, tachycardia, bradycardia, nausea, vomiting, abdominal pain, facial flushing, and dizziness. Syndrome of inappropriate secretion of antidiuretic hormone and priapism can occur rarely but are unique to specific substances. Severe overdose can cause seizures and cardiac toxicity, and the frequency of severe symptoms increases with coingestants.\(^{37}\)

**Fluoxetine.** About 45% of adults and 90% of children who overdose on fluoxetine alone develop no symptoms.\(^{33,38}\) Common symptoms of fluoxetine overdose include agitation, anxiety, restlessness, confusion, and hypomania.\(^{39}\) Other milder symptoms are tachycardia, drowsiness, tremor, nausea, and vomiting. In children, 5% develop diarrhea, and 5% develop sleepiness.\(^{7}\) QT\(_c\) prolongation, torsades de pointes, QRS widening, ventricular bigeminy, ventricular tachycardia, and seizures, with delayed onset 10 hours after ingestion, are rare with fluoxetine overdose.\(^{39-41}\)

**Fluvoxamine.** Tachycardia, bradycardia, hypotension, ECG abnormalities, seizures, liver function abnormalities, coma, and death have been reported with fluvoxamine.\(^{39}\) Status epilepticus and refractory hypotension also have been described with fluvoxamine toxicity.\(^{42,43}\)
Citalopram. Gastrointestinal upset; mild CNS changes, such as dizziness and somnolence; and mild autonomic symptoms, such as tachycardia, are observed with ingestions of citalopram less than 600 mg.2,8,44 QTc prolongation has been observed after an ingestion of 400 mg.44 At higher doses, QTc prolongation, QRS widening, ventricular fibrillation, seizures, and death have been reported.2,3,44 Seizures have been reported to start 14 hours after a citalopram and fluoxetine overdose.45 Seizures and QTc prolongation followed by torsades de pointes with cardiac arrest have been observed 13 hours following overdose.46,47 A prolonged observation period beyond the routine 6-hour observation period is suggested following citalopram overdose.

Escitalopram. Limited information is available about this enantiomer of citalopram. Ingestion of 600 mg is associated with only minor effects, including drowsiness, agitation, and tachycardia. No seizures were reported.48 Clinical toxicity is similar for overdose of citalopram when compared with escitalopram, with the most frequent symptoms being drowsiness, lethargy, tachycardia, and hypertension.49

Sertraline and Paroxetine. Mild symptoms after sertraline or paroxetine overdose are similar to symptoms with other SSRIs. Seizures and death have been reported with large doses of sertraline.50 In general, deaths attributed to SSRI overdose usually are associated with polydrug poisonings involving significant co-ingestants.8,50

Serotonin Syndrome

Serotonin syndrome is a constellation of signs and symptoms manifesting as autonomic, neuromuscular, and mental status changes (Box 149-4).1,31,32 Various drugs increase serotonin concentrations and serotoninergic neurotransmission (Table 149-5). Serotonin syndrome can occur when (1) a serotoninergic agent is added to an established medication regimen, (2) the dose of a serotoninergic agent is increased, or (3) high but usually therapeutic doses of a serotoninergic agent are taken.51 Sternbach suggested diagnostic criteria for the serotonin syndrome (Box 149-5); these also could include signs and symptoms of severe disease, such as muscle rigidity, clonus, hypertension, and tachycardia.51,53 “The Hunter criteria are diagnostic decision rules for diagnosing serotonin toxicity (Box 149-6).34

Diagnostic Strategies

A history of SSRI dosage increase, SSRI overdose, or SSRI use with an incompatible drug is the most helpful diagnostic indicator. Urine and blood toxicology tests for SSRIs are not readily available nor clinically useful.

Differential Considerations

The differential diagnosis of SSRI poisoning includes intoxications and pathologic conditions that cause sinus tachycardia, hypertension or hypotension, gastrointestinal upset, and seizures. In addition to these signs and symptoms secondary to SSRI overdose, SSRIs can produce serotonin syndrome (see...
Ernstbach's diagnostic criteria for serotonin toxicity criteria: INCREASED Drugs syndrome (Table 149-6).

The rapid onset of symptoms, and presence of clonus helps differentiate serotonin syndrome from neuroleptic malignant syndrome. A history of precipitating medication use (SSRI vs. neuroleptic), more sedative-hypnotic withdrawal, and strychnine poisoning should be considered in the differential diagnosis of serotonin syndrome. Clinically, serotonin syndrome can be difficult to distinguish from neuroleptic malignant syndrome. A neuroleptic has not been started or increased in dosage before the onset of the above signs and symptoms. Other etiologies, such as infections, intoxications, metabolic derangements, and withdrawal, have been ruled out.

*Not marketed in the United States.
LSD, D-lysergic acid diethylamide.

Boxes 149-5 and 149-6. CNS and other infections, intoxications (e.g., methamphetamine, cocaine, other sympathomimetics), metabolic derangements (e.g., thyroid storm), sedative-hypnotic withdrawal, and strychnine poisoning should be considered in the differential diagnosis of serotonin syndrome. Clinically, serotonin syndrome can be difficult to distinguish from neuroleptic malignant syndrome. A history of precipitating medication use (SSRI vs. neuroleptic), more rapid onset of symptoms, and presence of clonus helps differentiate serotonin syndrome from neuroleptic malignant syndrome (Table 149-6).

Management

Activated charcoal may be considered, but SSRI toxicity is mild and rare so the overall potential risk-benefit consideration would argue against this. Hemodialysis and hemoperfusion are not indicated because SSRIs have large volumes of distribution and are highly bound to plasma proteins. Forced diuresis is not helpful because minimal amounts of SSRIs and their active metabolites are eliminated in the urine.

Cardiovascular complications of serotonin toxicity include hypertension, sinus tachycardia, hypotension, and, rarely, ventricular dysrhythmias (Table 149-7). Hypertension and tachycardia are usually mild and transient and require no treatment. Hypotension is treated with isotonic crystalloids, and vasopressors are rarely necessary. Ventricular dysrhythmias should be treated with standard antidysrhythmic agents (e.g., lidocaine) (see Table 149-7). QRS prolongation with fluoxetine toxicity has responded to IV NaHCO₃ treatment.

Neurologic complications of SSRI overdose and serotonin syndrome are treated with benzodiazepines. Cyproheptadine, methysergide, chlorpromazine, and propranolol have been proposed as therapies, but have inconsistent effects. They have been used in isolated case reports of serotonin syndrome; however, none of these should be considered a proven therapy or diagnostic modality. Cyproheptadine is available as a liquid that can be given through a nasogastric tube, beginning with an adult dose of 4 to 8 mg followed by 4-mg doses every 1 to 4 hours as needed to a maximum of 32 mg/day. For children, 0.25 mg/kg/day is given in divided

**Box 149-5** STERNBACH’S DIAGNOSTIC CRITERIA FOR SEROTONIN SYNDROME

Adding a serotonergic agent to a patient’s established medication regimen or increasing the dose of a patient’s serotonergic agent.

At least three of the following signs and symptoms:

- Agitation
- Ataxia
- Diaphoresis
- Diarrhea
- Hyper-reflexia
- Hyperthermia
- Mental status changes (e.g., confusion, hypomania)
- Myoclonus
- Shivering
- Tremor

A neuroleptic has not been started or increased in dosage before the onset of the above signs and symptoms. Other etiologies, such as infections, intoxications, metabolic derangements, and withdrawal, have been ruled out.

**Box 149-6** HUNTER SEROTONIN TOXICITY CRITERIA: DECISION RULES

In the presence of a serotonergic agent:

1. If (spontaneous clonus = yes), then serotonin toxicity = yes
2. Else If (inducible clonus = yes) and [(agitation = yes) or (diaphoresis = yes)], then serotonin toxicity = yes
3. Else If (ocular clonus = yes) and [(agitation = yes) or (diaphoresis = yes)], then serotonin toxicity = yes
4. Else If (tremor = yes) and (hyper-reflexia = yes), then serotonin toxicity = yes
5. Else If (hypertonic = yes) and (temperature > 38°C) and [(ocular clonus = yes) or (inducible clonus = yes)], then serotonin toxicity = yes
6. Else serotonin toxicity = no

ACLS, advanced cardiac life support; IV NaHCO3, intravenous sodium bicarbonate.

doses every 6 hours to a maximum of 12 to 16 mg/day depending on the child’s age and weight. For children 2 to 6 years old, 2-mg doses can be given to a maximum of 12 mg/day based on the child’s weight. For children 7 to 14 years old, 4-mg doses can be given to a maximum of 16 mg/day. Complications are rare, but cyproheptadine should be avoided in anticholinergic overdoses.

Disposition

Asymptomatic patients with known or suggested SSRI overdose should have a 6-hour observation period with cardiac monitoring before psychiatric evaluation and disposition. Because ECG abnormalities and seizures have been reported later in the course of citalopram overdoses, these overdoses warrant observation up to 12 hours.45

Patients with known or suggested serotonin syndrome should be admitted to a monitored inpatient unit for 24 hours of observation. The clinical course and treatment of serotonin syndrome is less defined than that of SSRI overdose. Serotonin syndrome can be fatal and may require ICU admission for potential complications (e.g., ventricular tachycardia, hypotension, coma, hyperthermia, rhabdomyolysis).

■ MISCELLANEOUS ANTIDEPRESSANTS

Bupropion (Wellbutrin, Zyban), trazodone (Desyrel), nefazodone, venlafaxine (Effexor), desvenlafaxine (Pristiq), duloxetine (Cymbalta), and mirtazapine (Remeron) are the seven antidepressants approved by the U.S. Food and Drug Administration that constitute the miscellaneous category. Serzone was withdrawn because of liver toxicity. The structures and mechanisms of action of the miscellaneous antidepressants are unique and unrelated to the CAs, SSRIs, and MAOIs.

Bupropion

Bupropion is available in immediate-release, sustained-release, and newer extended-release formulations. A sustained-release formulation of bupropion is approved for smoking cessation. Bupropion is well absorbed from the gastrointestinal tract, reaches peak concentrations in 2 hours for immediate-release formulations, and has a maximal serum concentration of metabolites at 3 to 4 hours. The sustained-release peak concentration occurs at 3 hours for the parent compound and at 5 to 6 hours for the metabolites. The extended-release parent compound peak concentration occurs at 5 hours and at 7 to 8 hours for the metabolites. Bupropion is highly lipophilic, is extensively bound to plasma proteins, has a large volume of distribution (20–30 L/kg), and is metabolized predominantly by the liver. It has a half-life of 10 to 21 hours. Bupropion has three metabolites; two are active and clinically significant, with half-lives longer than 20 hours. Bupropion inhibits dopamine reuptake and enhances dopaminergic neurotransmission. To a lesser extent, bupropion also enhances noradrenergic neurotransmission by inhibition of norepinephrine reuptake and has very little serotonin reuptake inhibition.1

Clinical Features

Bupropion’s most significant toxic effect is seizure activity, which occurs not only with overdose but also when the maximal daily dose is exceeded.55 At the recommended daily dose of 450 mg of immediate-release bupropion, the seizure incidence is 0.4%.46 Incidence increases to 4% with dosages of 450 to 600 mg/day.1 The incidence of seizure with the sustained-release formulation is 0.1%. Seizures cannot be predicted from ECG or cardiac monitoring, and there is no correlation between seizures and the presence of other symptoms.77

Patients who overdose on bupropion alone do not usually develop hypotension or coma, but concomitant overdose with
benzodiazepines can lead to coma or respiratory failure. The rare deaths associated with bupropion overdose usually involve co-ingestants.58 Deaths due to bupropion alone have been reported, however.59 Tachycardia, vomiting, agitation, lethargy, tremor, confusion, and drowsiness are the most common symptoms in adults and teenagers; vomiting is the most common symptom in children.59 A significant number of intentional overdoses result in seizures.59 Seizures are usually single and self-limited, but about 5% of patients develop status epilepticus.59 Delayed onset of seizures has been recorded at 19 and 32 hours after ingestion of a sustained-release product.60,61 These seizures were thought to be caused by the slow-release nature of the parent product and accumulation of its active metabolites.61 Cardiovascular complications, including hypotension, bradycardia, intraventricular conduction delays, asystole, and death, have been recently reported.60,62 A pharmacobezoar was noted in one fatal sustained-release bupropion overdose.60

Management

Bupropion-induced seizures should be treated with IV benzo- diazepine (e.g., lorazepam, diazepam). Patients who have recurrent seizures or status epilepticus should be loaded with phenobarbital. Phenytin is not indicated. If neuromuscular blockade is needed, continuous electroencephalographic monitoring should be performed. Activated charcoal is not indicated routinely in an isolated bupropion ingestion, considering the often benign course and the risk of aspiration during a seizure. ECG conduction delays (e.g., QRS/QT, prolongation) resolve without specific treatment in many cases; however, they may require treatment if accompanied by hypotension or dysrhythmias.62,63,64 NaHCO3 has been used to successfully treat massive bupropion overdose with recurrent QRS widening and cardiac arrest.64 Effective circulation followed treatment with a lipid emulsion for refractory cardiovascular collapse following an overdose of bupropion and lamotrigine.65 Forced diuresis, hemodialysis, and hemoperfusion do not enhance elimination. Patients with an overdose of immediate-release bupropion require 8 hours of observation because seizures have occurred 8 hours after this overdose in the absence of other signs and symptoms.59 With a sustained-release preparation, observation should be at least 12 hours. Because of limited data about overdose with the extended-release formula, a 24-hour observation period seems reasonable, given the finding of late onset seizures up to 24 hours following overdose of bupropion XL.66 All of these observation periods should be extended if patients are otherwise symptomatic or experience a seizure during the observation period because of the risk of subsequent seizures.

Trazodone and Nefazodone

Trazodone and nefazodone are well absorbed from the gastrointestinal tract, reach peak concentration in 1 to 2 hours, are extensively bound to plasma proteins, and are metabolized predominantly by the liver. The half-life of trazodone is about 6 hours and nefazodone about 4 hours.1,67 The major action of trazodone and nefazodone is inhibition of reuptake of serotonin, but neither is an SSRI.1,59 They do not have antimuscarinic or antihistaminic effects.7,59 Other pharmacodynamic effects include alpha1-adrenoreceptor blockade, inhibition of norepinephrine reuptake, and postsynaptic serotonin1-receptor blockade.1 Hypotension in overdose is caused by alpha1-adrenoreceptor blockade.63 Trazodone and nefazodone overdoses are less toxic than CA and MAOI overdoses.59,67,68

Clinical Features

Clinical presentation of trazodone overdose is similar to SSRI overdose.67 Cardiac toxicity has been reported with trazodone, but is rare. Trazodone also has been implicated in serotonin syndrome.51,54 The most common manifestations of trazodone overdose are orthostatic hypotension with lightheadedness, drowsiness, lethargy, ataxia, nausea, and vomiting.67 There are isolated reports of priapism, respiratory arrest, prolonged QTc, ventricular dysrhythmias including torsades de pointes, bradycardia, hypotension, seizures, coma, and death. When trazodone overdose occurs with coingestants, morbidity and mortality rates are increased.67,68 Because the two drugs are functionally similar, nefazodone most likely has similar toxicity to trazodone.

Management

Hypotension responds to boluses of IV crystalloids and usually does not require vasopressors.67 Rare ventricular dysrhythmias should be treated with standard cardiac therapy. Neurologic complications of trazodone poisoning are treated similarly to neurologic complications of CAs (see Table 149-3). There is no proven efficacy of activated charcoal, and this is usually a more benign ingestion. Based on the pharmacokinetic data, forced diuresis, hemodialysis, and hemoperfusion have no benefit. After 6 hours of observation, asymptomatic overdose patients can receive psychiatric evaluation and disposition.

Venlafaxine, Desvenlafaxine, and Duloxetine

Venlafaxine is well absorbed from the gastrointestinal tract, reaches peak concentrations in 2 hours, has a large volume of distribution (=7.5 L/kg), and undergoes extensive hepatic metabolism to form the active metabolite O-desmethylvenlafaxine (ODV). The half-life of venlafaxine is about 5 hours, and the half-life of ODV is about 11 hours.1 The extended-release preparation, Effexor XR, reaches a peak concentration 6 to 7 hours after therapeutic dosing.69 Venlafaxine and ODV inhibit reuptake of serotonin to a greater extent than norepinephrine and dopamine.1,69 There is a dose-dependent blockade of sodium channels.69,70 Desvenlafaxine, an oxidative metabolite of venlafaxine, is new, and information about its mechanism of action is limited at this time.

Duloxetine is well absorbed from the GI tract. It reaches peak concentration in about 6 hours if not taken with food and about 10 hours if taken with food. It has a large volume of distribution, is highly protein-bound, and has a half-life of 11 hours. The metabolites do not have significant pharmacologic activity. At low doses, duloxetine inhibits the reuptake of serotonin. At medium doses it inhibits serotonin and norepinephrine reuptake. At high doses, the reuptake of serotonin, norepinephrine, and dopamine is inhibited.70

Clinical Features

Most venlafaxine overdose patients are asymptomatic. Somnolence and sinus tachycardia are the most common symptoms. Seizures, life-threatening hypotension, QRS and QT, prolongation, and death from venlafaxine overdose have been reported but occur more often in combination with co-ingestants.60,71,72 Venlafaxine may not be as safe in overdose, however, as other serotoninergic drugs.2,50,66 Rhabdomyolysis, hepatic failure, and renal failure have all been reported following venlafaxine overdose.2 Massive venlafaxine overdose has resulted in arrhythmogenic death.73 Serotonin syndrome has occurred when venlafaxine was used with MAOIs.80
The most common clinical effects to duloxetine exposure in one case series were neurologic. This included drowsiness or lethargy, irritability, agitation, tachycardia, confusion, and hallucinations. Drowsiness or lethargy was the most common effect. Tachycardia and nausea and vomiting were the next most common.\(^{75}\)

**Management**

Standard supportive care is the foundation of overdose treatment. This includes NaHCO\(_3\) for an increased QRS duration in the setting of hypotension. The rare instances of hypotension without QRS widening are treated with IV fluids, dopamine, and norepinephrine. There is no antidote. Cyproheptadine has been used in serotonin syndrome associated with venlafaxine and duloxetine. Benzodiazepines have been effective for venlafaxine-associated seizures. Forced diuresis, hemodialysis, and hemoperfusion have no role. After 6 hours of observation, longer for duloxetine, asymptomatic overdose patients can receive psychiatric evaluation and disposition.

**Mirtazapine**

Mirtazapine is well absorbed from the gastrointestinal tract, reaches peak concentrations within 2 hours after therapeutic doses, and is highly protein-bound. It is extensively metabolized in the liver to one active and two inactive metabolites. The elimination half-life of mirtazapine is 20 to 40 hours; the half-life for the active demethylated metabolite, normirtazapine, is about 19 hours.\(^{60}\) Mirtazapine blocks presynaptic alpha\(_2\)-adrenergic receptors, increasing release of 5-HT and norepinephrine.\(^{1,74,75}\) Mirtazapine blocks 5-HT\(_2\) and 5-HT\(_3\) receptors with high potency but has little effect on 5-HT\(_1\) receptors; this results in fewer gastrointestinal effects compared with SSRIs.\(^{1,74,75}\) To a lesser extent, mirtazapine antagonizes H\(_1\) (histaminic), muscarinic, and peripheral alpha\(_1\)-adrenergic receptors; this can cause sedation, tachycardia, and hypotension.\(^{1,74}\) Mirtazapine has fewer anticholinergic, antihistaminic, and antiadrenergic effects than CAs.

**Clinical Features**

In the few cases reported, somnolence, dizziness, anxiety, confusion, moderate hypotension, slight increase in systolic blood pressure, and mild tachycardia have occurred and resolved without specific treatment. No seizures or significant ECG changes were reported in two reports of isolated mirtazapine overdoses.\(^{76,77}\) Sedation, tachycardia, and cognitive disorganization have been observed, but without permanent sequelae.\(^{76,77,78}\) A case of mirtazapine along with co-ingestants was fatal.\(^{79}\)

### MONOAMINE OXIDASE INHIBITORS

Many drugs inhibit monoamine oxidases (MAOs).\(^1\) Six drugs with significant MAO inhibition are marketed in the United States (Table 149-8).\(^7\) MAOIs are well absorbed from the gastrointestinal tract, reach peak concentrations in 0.5 to 2.5 hours, are extensively bound to plasma proteins, and have relatively large volumes of distribution.\(^{80}\) Tranylcypromine and selegiline have active metabolites that include significant amounts of amphetamine and methamphetamine.\(^{35}\) Selegiline is now available in transdermal patch and oral dissolving tablet formulations. Minimal amounts of MAOIs are eliminated in the urine as unchanged drugs.

The MAO isoenzymes, MAO-A and MAO-B, inactivate direct-acting endogenous, biogenic amines, such as epinephrine, norepinephrine, and serotonin, as well as indirect-acting exogenous, biogenic amines, such as tyramine.\(^{80-82}\) Effects of MAOIs include (1) inhibition of MAO; (2) MAOI effect on indirect sympathomimetics, such as amphetamine and methamphetamine, with the potential for enhanced CNS and peripheral nervous system sympathomimetic toxicity; (3) eventual depletion of norepinephrine stores; and (4) inhibition of pyridoxine phosphokinase and pyridoxine (vitamin B\(_6\))-containing enzymes (Box 149-7).\(^{80,81}\)

### Clinical Features

The three presentations of MAOI toxicity are (1) MAOI overdose, (2) MAOI-food or MAOI-beverage interactions, and (3) MAOI-drug interactions.\(^{80}\) These three presentations have different precipitating events, time to onset of symptoms, duration of symptoms, and major sign and symptom complexes (Table 149-9). All three presentations involve excessive sympathetic activity. The most common cardiovascular complications of interactions between foods, beverages, or drugs and MAOIs are hypertension and tachycardia. Reflex bradycardia can occur with severe hypertension.

### Overdose

The clinical course of severe MAOI overdose occurs in four phases: (1) asymptomatic or latent, (2) neuromuscular and cardiovascular excitation with sympathetic hyperactivity, (3) CNS depression and cardiovascular collapse with hypotension and bradycardia late in severe overdoses, and (4) secondary complications caused by previous phases.\(^{80}\) Onset of signs and symptoms after acute overdose usually occurs in 6 to 12 hours, but may be delayed 24 hours. Symptoms in acute MAOI overdose last for days (Table 149-10).

*Irreversible drugs have a much longer effect.
Seizures, coma, and muscular rigidity impair patients’ abilities to keep airways patent, decrease ventilatory drive, and can produce rigid chest walls. Seizures, agitated delirium, myoclonus, muscular rigidity, and hyperthermia can result in rhabdomyolysis. An overdose of 2 mg/kg (170 mg in an adult) can be lethal. Occasionally, hypotension, bradycardia, and asystole have been reported late in severe poisonings. Initial release of norepinephrine can result in a decrease in the amount available for subsequent discharge from presynaptic vesicles. This situation may explain late CNS depression and cardiovascular collapse after earlier stimulatory phases of MAOI overdose. Another potential cause of late brady cardiac dysrhythmias is hyperkalemia from rhabdomyolysis. Long-term use of phenelzine has been associated with a sensorimotor peripheral neuropathy, probably from pyridoxine depletion. Myocarditis due to massive phenelzine overdose has also been reported.

### Monoamine Oxidase Inhibitor–Food or Monoamine Oxidase Inhibitor–Beverage Interactions

Onset of sympathetic signs and symptoms with MAOI-food or MAOI-beverage interactions occurs in minutes to hours because ingested tyramine acts on the adrenal medulla to release endogenous biogenic amines (see Box 149-7). These interactions last only a few hours because of tyramine’s short duration of action.

### Monoamine Oxidase Inhibitor–Drug Interactions

Signs and symptoms of MAOI-drug interactions are sympathetic storm or the serotonin syndrome and begin minutes to hours after ingesting precipitating drugs (see Boxes 149-4 to 149-6 and Tables 149-5 and 149-6). Most MAOI-drug interactions occur in patients who are taking MAOIs regularly on an ongoing basis and ingest incompatible drugs, such as indirect-acting and mixed-acting (direct/indirect-acting) sympathomimetics, methylxanthines, antidepressants, opioids (e.g., meperidine), and other drugs that can cause serotonin syndrome (see Table 149-5; Box 149-8). These drugs produce excessive concentrations of endogenous biogenic amines that are not degraded because of MAO inhibition. Duration of MAOI-drug interactions is hours to days, depending on the precipitant’s duration of effect, half-life, and formulation (e.g., sustained release, delayed release).

### Differential Considerations

A recent or distant history of MAOI use alone or with food is the most helpful diagnostic clue. Urine and blood toxicology tests for MAOI levels are not readily available and are of little clinical value. The differential diagnosis of MAOI poisoning includes illnesses (e.g., thyroid storm, meningitis) and sympathomimetic intoxications (e.g., cocaine, amphetamines, theophylline, nicotine). Hypertensive emergencies, malignant hyperthermia, and heatstroke also are considerations in the differential diagnosis. Effects of MAO inhibition persist for...
weeks after cessation of MAOIs because MAO enzyme activity must be regenerated by synthesis of new MAO isoenzymes. Significant potential for MAOI toxicity can persist long after the drug has left the body.

**Management**

Sinus tachycardia does not usually require treatment. Beta-blockers can cause unopposed α₁-adrenoreceptor stimulation of the peripheral vasculature with vasoconstriction and worsening of the hypertension. Beta-blockers also can exacerbate the hypotension and bradycardia that can occur later in severe MAOI poisonings. Calcium channel blockers also are relatively contraindicated because of the potential for hypotension and bradycardia.

Hypertension associated with MAOI toxicity can range from mild to life-threatening hypertensive emergencies. Mild hypertension does not require treatment. Hypertension with signs of impending or ongoing target-organ damage or with reflex bradycardia mandates treatment with sodium nitroprusside or phentolamine; both have rapid onset, easy titratability, and rapid resolution of effect when stopped, if hypotension develops later. An initial 5-mg bolus (adults) or 0.02 mg/kg to 0.1 mg/kg (children) of phentolamine is given over 1 minute. The initial IV bolus can be repeated at 5- to 10-minute intervals as needed to lower the blood pressure to the desired range, followed by a phenolamine infusion to maintain the pressure. The initial dose of nitroprusside is 0.5 µg/kg/min, titrated to effect with a maximum rate of 10 µg/kg/min. Sodium thiosulfate can be used with continuous infusions of nitroprusside to prevent cyanide toxicity.

Reflex bradycardia is a beneficial compensatory response to significant, acute hypertension and decreases cardiac output; bradycardia should not be treated, unless it is associated with significant hypotension. Hypotension caused by MAOI toxicity usually occurs late in severe intoxications. If hypotension is associated with bradycardia, IV atropine should be administered until the bradycardia and hypotension resolve or a vagolytic dose of atropine has been reached (3 mg in adults or 0.04 mg/kg in children, with a minimum dose of 0.1 mg in children). Hypotension without bradycardia should be treated with IV isotonic crystalloids. A pacemaker is necessary for symptomatic bradycardia with accompanying hypotension that does not respond to atropine or agents such as epinephrine, dobutamine, or norepinephrine. Initially a transcutaneous pacemaker can be used. Symptomatic, treatment-resistant bradycardia is often prolonged, however, and a transvenous pacemaker is optimal. Lidocaine is the drug of choice for ventricular dysrhythmias associated with MAOI toxicity.

Neurologic complications of MAOI toxicity are treated similarly to neurologic complications of CA toxicity (see Table 149-3). Danzol, 2.5 mg/kg IV initially and repeated every 6 hours for 24 hours, seemed to be useful in a phentolamine overdose accompanied by life-threatening hyperthermia. IV benzodiazepines may be used to control agitation. There is no antidote for MAOI toxicity, and forced diuresis, hemodialysis, and hemoperfusion are not effective.

**Disposition**

The severity of acute MAOI overdoses is easily underestimated because signs and symptoms usually are not evident during the first 6 to 12 hours and may be delayed in onset for 24 hours. Patients with significant MAOI overdose or suggested serotonin syndrome should be observed for 24 hours. Symptomatic patients with known or suggested MAOI interactions with food, beverages, or drugs should be admitted to an ICU for at least 24 hours. Patients with possible food or drug interactions can be discharged if they remain asymptomatic for 6 hours.

**DISCONTINUATION SYNDROME**

Discontinuation syndromes with MAOIs, CAs, SSRIs, and various atypical antidepressants including venlafaxine and mirtazapine have been described. A discontinuation syndrome has not yet been described for citalopram. Symptoms depend on the agent and its mechanism of active action. With some SSRIs, insomnia, nausea, headache, sensory disturbances, hyperarousal, anxiety, agitation, tachycardia, and tremor have been reported.

Restarting the drug and instituting a gradual taper over days to weeks generally reverses the discontinuation syndrome. Augmenting a drug that has a short half-life with another that has a long half-life may help to overcome the discontinuation syndrome. Confusion and psychotic symptoms caused by stopping MAOIs may require hospital admission, restarting the MAOI, or treating with an antipsychotic medication. Atropine and benztropine can help treat CA discontinuation symptoms because these symptoms reflect cholinergic rebound.

A neonatal discontinuation syndrome, after in utero exposure to an SSRI in the third trimester of pregnancy, was described. Symptoms included irritability, constant crying, shivering, increased tonus, eating and sleeping difficulties, and seizures. Signs and symptoms began within a few days after birth and lasted 1 month.
### KEY CONCEPTS

- A patient with CA poisoning can deteriorate quickly.  
- When in doubt, it is better to perform endotracheal intubation to prevent aspiration, hypoxia, or hypercarbia that can increase significantly the morbidity and mortality associated with CA poisoning.  
- NaHCO$_3$ treats cardiac conduction abnormalities and negative inotropic effects of CA poisoning that result in ventricular dysrhythmias and hypotension with a wide QRS complex.  
- The fatality rate for SSRI overdose is much lower than that for CA overdose.  
- If serotonin syndrome is suggested, the patient should be admitted to a monitored unit for 24 hours of observation.  
- Medication lists should be scrutinized for serotonin-enhancing drugs, and medications such as meperidine should be avoided in patients with SSRI overdose.  
- Bupropion poisoning should be considered when seizures occur.  
- Trazodone toxicity should be considered in a patient with priapism.  
- If MAOI overdose is suggested or diagnosed, admission for 24 hours of observation is indicated, even if the patient is initially asymptomatic.  
- MAOI toxicity should be considered in patients with hyperthermia, altered mental status, or muscular rigidity, such as those with meningitis, thyroid storm, neuroleptic malignant syndrome, malignant hyperthermia, and heatstroke.  
- Hyperthermia must be treated aggressively to limit morbidity and mortality.  
- The source of a food, beverage, or drug interaction with an MAOI should be identified to avoid recurrence and future complications.

### ACKNOWLEDGMENT

The author would like to thank Frank G. Walter, MD, who was an author in the last three editions.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Cardiovascular drugs rank among the most common causes of poisoning fatalities, both in children (third leading cause) and in adults (fifth leading cause). Of the scores of cardiovascular drugs, three—digitalis, propranolol, and verapamil—account for the majority of fatalities.

**DIGITALIS**

**Perspective**

Digitalis is derived from the foxglove plant, *Digitalis purpurea* (Fig. 150-1). Despite centuries of experience with digitalis, chronic and acute poisonings still occur. Dr. Benjamin Rush wrote in 1797, “I suspect the cases in which [digitalis preparations] were useful to have been either so few or doubtful and that the cases they had done harm were so much more numerous and unequivocal as justly to banish them from the *Materia Medica.*” Medication errors and toxic effects account for the most common causes (44%) of preventable iatrogenic cardiac arrests.

**Principles of Disease**

**Pathophysiology**

In therapeutic doses, digitalis has two effects: (1) increasing the force of myocardial contraction to increase cardiac output in patients with heart failure; and (2) decreasing atrioventricular (AV) conduction to slow the ventricular rate in atrial fibrillation. The biochemical basis for its first effect is an inhibition of membrane sodium-potassium adenosine triphosphatase (ATPase), which increases intracellular sodium and calcium and increases extracellular potassium. At therapeutic doses, the effects on serum electrolyte levels are minimal. With toxic levels, digitalis paralyzes the Na-K pump, potassium cannot be transported into cells, and serum potassium can rise as high as 13.5 mEq/L.

Digitalis exerts direct and indirect effects on sinoatrial (SA) and AV nodal fibers. At therapeutic levels, digitalis indirectly increases vagal activity and decreases sympathetic activity. At toxic levels, digitalis can directly halt the generation of impulses in the SA node, depress conduction through the AV node, and increase the sensitivity of the SA and AV nodes to catecholamines. Catecholamines, whether endogenous or administered by physicians to treat bradycardias or hypotension, probably play an important role in digitalis toxicity, and iatrogenic interventions may contribute to digitalis toxicity. Because bradycardias or tachycardias can appear and alternate in the same patient, administering one class of drugs to treat tachycardias may later contribute to more refractory bradycardias and AV block.

Digitalis also exerts three primary effects on Purkinje’s fibers: (1) decreased resting potential, resulting in slowed phase 0 depolarization and conduction velocity; (2) decreased action potential duration, which increases sensitivity of muscle fibers to electrical stimuli; and (3) enhanced automaticity resulting from increased rate of phase 4 depolarization and delayed after depolarizations. These mechanisms account for an increase in premature ventricular contractions, the most common manifestation of digitalis toxicity. At toxic extremes, these effects result in a dangerous sensitivity to mechanical and electrical stimulation. Iatrogenic interventions with pacemaker catheters and cardioversion can result in asystole, ventricular tachycardia, and ventricular fibrillation.

Unlike most cardiovascular drugs, digitalis can produce virtually any dysrhythmia or conduction block, and bradycardias are as common as tachycardias (Box 150-1). Unfortunately, none is peculiar to digitalis, and they can all occur in the setting of ischemic and other heart disease in the absence of digitalis. Digitalis intoxication remains a clinical rather than an electrocardiographic diagnosis.

The volume of distribution (Vd) of digoxin is 5 L/kg for adults but varies from 3.5 L/kg in premature infants to 16.3 L/kg in older infants. This indicates that only a small fraction of digitalis remains in the intravascular space, and the drug is highly concentrated in cardiac tissue. The myocardial-to-serum ratio at equilibrium ranges from 15:1 to 30:1. The Vd for digitoxin is 0.5 L/kg.

The elimination half-life of digoxin, which is primarily excreted in the urine, is 30 hours, and the half-life of digitoxin, which is metabolized in the liver, is 7 days. Whereas digoxin undergoes only a small enterohepatic circulation, that for digitoxin is large, and multiple-dose charcoal treatment is clearly indicated for the latter.

Protein binding varies from 25% for digoxin to 95% for digitoxin. The significant protein binding and large volume of distribution suggest that hemodialysis, hemoperfusion, and exchange transfusion are ineffective. The long half-lives suggest that temporizing measures such as pacemakers, atropine, and antidysrhythmic drugs might in the end cost more time, money, and lives than simply giving Fab fragments initially.
Figure 150-1. The foxglove plant, from which digitalis is derived.

**Box 150-1**  
**Dysrhythmias Associated with Digitalis Toxicity**

**Nonspecific**
- PVCs, especially bigeminal and multiform
- First-, second- (Wenckebach’s), and third-degree AV block
- Sinus bradycardia
- Sinus tachycardia
- Sinoatrial block or arrest
- Atrial fibrillation with slow ventricular response
- Atrial tachycardia
- Junctional (escape) rhythm
- AV dissociation
- Ventricular bigeminy and trigeminy
- Ventricular tachycardia
- Torsades de pointes
- Ventricular fibrillation

**More Specific, but Not Pathognomonic**
- Atrial fibrillation with slow, regular ventricular rate (AV dissociation)
- Nonparoxysmal junctional tachycardia (rate 70–130 beats/min)
- Atrial tachycardia with block (atrial rate usually 150–200 beats/min)
- Bidirectional ventricular tachycardia

**Box 150-2**  
**Factors Associated with Increased Risk of Digitalis Toxicity**

- Renal insufficiency
- Heart disease
  - Congenital heart disease
  - Ischemic heart disease
  - Congestive heart failure
  - Myocarditis
- Electrolyte imbalance
  - Hypokalemia or hyperkalemia
  - Hypomagnesemia
  - Hypercalcemia
- Alkalosis
- Hypothyroidism
- Sympathomimetic drugs
- Cardiotoxic co-ingestants
  - Beta-blockers
  - Calcium channel blockers
  - Tricyclic antidepressants
- Drug interactions
  - Quinidine, amiodarone
  - Erythromycin
  - Verapamil, diltiazem, nifedipine
  - Captopril
- Elderly woman

**Box 150-3**  
**Noncardiac Symptoms of Digitalis Intoxication in Adults and Children**

**General**
- Weakness
- Fatigue
- Malaise

**Gastrointestinal**
- Nausea and vomiting
- Anorexia
- Abdominal pain
- Diarrhea

**Ophthalmologic**
- Blurred or snowy vision
- Photophobia
- Yellow-green chromatopsia (also red, brown, blue)
- Transient amblyopia, diplopia, scotomata, blindness

**Neurologic**
- Dizziness
- Headache
- Confusion, disorientation, delirium
- Visual and auditory hallucinations
- Paranoid ideation, acute psychosis
- Somnolence
- Abnormal dreams
- Paresthesias and neuralgia
- Aphasia
- Seizures

Multiple drugs and disease states can negatively alter absorption, Vd, protein binding, and elimination and render the heart more susceptible to digitalis toxicity. The factors listed in Box 150-2 are especially important risk factors in chronic intoxication.

**Clinical Features**

The symptoms and signs of chronic digitalis intoxication are nonspecific. The most common symptoms—reported in more than 80% of cases—are nausea, anorexia, fatigue, and visual disturbance, but a variety of gastrointestinal, neurologic, and ophthalmic disturbances have also been linked to digitalis (Box 150-3). One should consider digitalis intoxication in any patient on maintenance therapy who develops consistent

Differential Considerations

No sign or symptom, including dysrhythmia, is unique to digitalis poisoning, so the differential diagnosis is broad. Intrinsic cardiac disease as well as other cardiotoxic drugs must be considered. Central nervous system (CNS) depression or confusion may be secondary to various drugs and toxins as well as infection, trauma, inflammation, and metabolic derangements. Visual disturbances, should they be binocular, are often not reported by the patient, and the clinician should ask directly about them. Gastrointestinal disturbances are common and nonspecific and may be misdiagnosed as gastritis, enteritis, or colitis.

Management

With the availability of digoxin-specific fragment antigen-binding (Fab) antibodies (Digibind and DigiFab), all other therapies are considered temporizing.

There is no evidence to support gastric emptying for the treatment of digoxin overdose. Oral overdoses historically have been treated with activated charcoal, if it could be administered within 1 hour of ingestion, but no improvement in outcome has been established. Similarly, multidose charcoal has historically been used for digitoxin toxicity because of its prominent 26% enterohepatic circulation. This also is without proven benefit, however, and in any case, considerations of multidose charcoal are irrelevant with the widespread availability of antidigoxin antibody treatment as a specific antidote.

Electrolyte Correction

In cases of chronic intoxication, often exacerbated by hypokalemia, raising the serum potassium level to 3.5 to 4 mEq/L is an important early treatment. Potassium can be administered orally (which is safer) or intravenously (IV) although a rate more rapid than 10 to 40 mEq/hour is dangerous.

In acute poisoning, serum potassium may begin to rise rapidly within 1 to 2 hours of ingestion, potassium should be withheld, even if mild hypokalemia is measured initially. A serum potassium level greater than 5 mEq/L warrants consideration of digitalis antibody (ovine Fab fragment) treatment. If digitalis antibodies are not immediately available, severe hyperkalemia should be treated with IV glucose, insulin, and sodium bicarbonate. Although hypercalcemia can exacerbate digitalis intoxication, recent studies indicate that IV calcium can be safely given for hyperkalemia in the setting of digitalis intoxication. Calcium salts should be administered over several minutes through a secure peripheral IV site or through a central venous catheter.

Many patients on diuretic therapy are also magnesium-depleted, even when the measured serum magnesium level is normal. If significant magnesium depletion is suggested, 1 to 2 g of magnesium sulfate can be given over 10 to 20 minutes (child: 25 mg/kg), followed by a constant infusion of 1 to 2 g/hr. Patients must be closely monitored for respiratory depression, which is usually preceded by progressive loss of deep tendon reflexes. Hypermagnesemia can exacerbate digitalis toxicity, but magnesium has been reported to reverse digoxin-induced tachydysrhythmias. It is prudent to infuse magnesium slowly and stop the infusion if heart block or bradydysrhythmias develop. Avoid magnesium in patients with renal failure. The role of magnesium in bradydysrhythmias and conduction blocks is less clear but probably dangerous because hypermagnesemia can impair impulse formation and AV conduction.

Atropine

Atropine is generally used for severe bradycardia and advanced AV block, with mixed results. Generally, an external or
transvenous pacemaker should be readied when bradycardia or AV block appears.

**Pacing**

Transvenous pacing has been a mainstay of treatment for several decades, but the catheter may induce ventricular tachydysrhythmias in a myocardium made irritable by digitalis. Iatrogenic accidents of cardiac pacing are frequent (14/39, 36%) and often fatal (5/39, 13%). It may be safer to temporize with an external rather than a transvenous pacemaker while waiting for Fab fragments to take effect. Cardioversion and defibrillation can cause asystole after attempts to treat tachydysrhythmias. Lower energy settings, such as 25 to 50 J, may be less hazardous.

**Carotid Sinus Massage**

Carotid sinus massage may result in bradyasystole and cardiac arrest in the setting of digitalis toxicity.

**Phenytoin and Lidocaine**

Phenytoin and lidocaine are believed to be the safest of the antidysrhythmic drugs for controlling tachydysrhythmias in the setting of digitalis intoxication. Phenytoin may enhance AV conduction. Phenytoin has been infused at 25 to 50 mg/min to a loading dose of 10 to 15 mg/kg. Lidocaine can be given initially at a dosage of 1 to 3 mg/kg over several minutes, followed by an infusion of 1 to 4 mg/min (30–50 µg/kg/min).

**Fab Fragments (Digibind or Digifab)**

The mortality rate before Fab fragment therapy was 23%, despite all of the interventions described. Fab fragment treatment is well established in both chronic and acute poisonings, with a 90% response rate. Nonresponders usually receive too little antibody or receive it too late. Other nonresponders are compromised by underlying heart or multisystem disease.

**Digitalis-toxic dysrhythmias**

Digitalis antibodies are derived from sheep immunized with digoxin. Because the more antigenic Fab fragments are discarded, allergic reactions are less than 1% and routine skin testing is unnecessary. Reactions have included erythema, urticaria, and facial edema, all of which are responsive to the usual treatment. Other expected reactions to Fab fragment neutralization of digitalis include hypokalemia, exacerbation of congestive heart failure, or increase in ventricular rate with atrial fibrillation.

Fab fragment treatment is best reserved for cases of serious cardiovascular toxicity rather than for routine or prophylactic administration of higher than expected serum levels. The primary indication for antibody treatment in cases of acute poisoning is hyperkalemia with a serum potassium level greater than 5.5 mEq/L or electrocardiographic changes. Although toxicity increases with greater body load, there is no clear correlation with amount ingested, especially in children, and many patients with large ingestions or high serum levels become only mildly symptomatic. Fab fragment therapy should be used before transvenous pacing, which carries significant risk.

The median time to initial response is 19 minutes after completion of the Fab infusion, but complete resolution of digitalis-toxic rhythms may require hours. Late administration of Fab fragments has resuscitated 54% of patients who have suffered cardiac arrest. This antidote should be considered whenever hemodynamic compromise attends a digitalis-toxic dysrhythmia or heart block.

**RECOMMENDATIONS FOR ADMINISTRATION OF DIGITALIS ANTIBODY FRAGMENTS**

**Adults**

1. Severe ventricular dysrhythmias
2. Progressive and hemodynamically significant bradydysrhythmias unresponsive to atropine
3. Serum potassium greater than 5 mEq/L
4. Rapidly progressive rhythm disturbances or rising serum potassium level
5. Co-ingestion of cardiotoxic drugs such as beta-blockers, calcium channel blockers, or tricyclic antidepressants
6. Ingestion of plant known to contain cardiac glycosides plus severe dysrhythmias (rare)
7. Acute ingestion greater than 10 mg plus any one of factors 1 through 6 above
8. Steady-state serum digoxin greater than 6 ng/mL plus any one of factors 1 through 6 above

**Children**

1. Ingestion of greater than 0.1–0.3 mg/kg or steady-state digoxin greater than 5 ng/mL plus rapidly progressive symptoms or signs of digitalis intoxication or potentially life-threatening dysrhythmias or conduction blocks or serum potassium greater than 6 mEq/L
2. Co-ingestion of other cardiotoxic drugs with additive or synergistic toxicity
3. Ingestion of plant known to contain cardiac glycosides plus severe dysrhythmias (rare)

**BOX 150-5** SAMPLE CALCULATION OF DIGIBIND OR DIGIFAB BASED ON INGESTED DOSE OF DIGOXIN OR DIGITOXIN

Case: A toxic-appearing 40-year-old woman has ingested fifty 0.25-mg digoxin tablets

- Body load = amount ingested × 0.8 (bioavailability of digoxin tablets)
  
  = 12.5 mg × 0.8 = 10 mg

- Dose of digoxin Fab fragments (in vials) = 10 mg + 0.5 mg bound per vial
  
  = 20 vials

*Formula from GlaxoSmithKline 2008.

**BOX 150-6** SAMPLE CALCULATION OF DIGIBIND OR DIGIFAB BASED ON STEADY-STATE DIGOXIN CONCENTRATION

Case: A toxic-appearing 4-year-old child weighing 20 kg has a digoxin level of 16 ng/mL 8 hr after ingestion of an unknown number of digoxin tablets

- Dose (in number of vials) = (serum digoxin concentration × weight in kg) ÷ 100
  
  = (16 × 20) ÷ 100
  
  = approximately 3 vials

*Formula from GlaxoSmithKline 2008; assumes $V_d = 5 \text{ L/kg}$.

**BOX 150-7** CALCULATION BASED ON STEADY-STATE DIGITOXIN CONCENTRATION

Case: A toxic-appearing 70-year-old man weighing 80 kg has a digitoxin level of 200 ng/mL (therapeutic = 10 to 35 ng/mL)

- Dose (in number of vials) = (serum digitoxin concentration × weight in kg) ÷ 1000
  
  = (200 × 80) ÷ 1000
  
  = 16 vials

*Formula from GlaxoSmithKline 2008; $V_d = 5 \text{ L/kg}$.

---

Dosage calculation and administration errors account for more pediatric digitalis intoxication and death than does accidental oral ingestion. Therapeutic errors—especially accidental IV overdoses—often result in death within 1 to 4 hours.

Signs and symptoms in children with digoxin poisoning are somewhat different (Table 150-2). Vomiting, somnolence, and obtundation is more common than in adults.14,18 A CNS depression, in the absence of a history, might lead the clinician to suspect narcotic or sedative-hypnotic overdose, or even non-toxicologic causes such as head injury, metabolic disorder, or CNS infection. Conduction disturbances and bradycardias are more common than ventricular dysrhythmias in children, especially with acute ingestion.6,14

### Disposition

All patients who are symptomatic for digitalis intoxication with hyperkalemia, dysrhythmia, AV block, or significant comorbidity should be admitted to the hospital or the emergency department observation unit for at least 12 hours of continuous cardiac monitoring. Patients with an acute ingestion of a large quantity of digoxin should be treated with Fab and admitted to an intensive care unit or coronary care unit until stabilized. All patients treated with antibodies require admission to an intensive care unit or a coronary care unit until their toxicity resolves.

### BETA-ADRENERGIC BLOCKERS

#### Perspective

Beta-adrenergic blocking drugs became widely used in Europe in the 1960s for treatment of dysrhythmias. Their antihyper-tensive effects were later appreciated, and by the 1970s they were one of the most widely prescribed classes of drugs in the United States. Current indications include supraventricular dysrhythmias, hypertension, angina, thyrotoxicosis, migraine, and glaucoma. Overdose of propranolol is the most deadly, followed by acebutolol, oxprenolol, and alprenolol.23

#### Pathophysiology

Beta-blockers structurally resemble isoproterenol, a pure beta-agonist. They competitively inhibit endogenous catehol-
amines such as epinephrine at the beta-receptor. Catecholamine stimulation of beta-receptors results in the activation of adenyl cyclase, converting adenosine monophosphate (AMP) to cyclic AMP, which augments myocardial contraction (inotropy), enhances cardiac conduction (dromotropy), and accelerates heart rate (chronotropy). These are all beta_1 effects. Complex beta_2 effects include vascular (smooth muscle relaxation and vasodilation), liver (glycogenolysis, gluconeogenesis), lung (bronchodilation), adipose tissue (release of free fatty acids), and uterus (smooth muscle relaxation) effects. Equally important properties, which vary from one beta-blocker to another, include cardioselectivity, membrane-stabilizing effect, lipophilicity, and intrinsic sympathomimetic activity (Table 150-3). Although cardioselectivity is lost in overdose, cardioselective beta-blockers such as atenolol, metoprolol, and esmolol are associated with a lower mortality rate than propranolol, the oldest beta-blocker.

Beta-blockers are rapidly absorbed after oral ingestion, and the peak effect of normal-release preparations occurs in 1 to 4 hours. Hepatic metabolism on first pass results in significantly less bioavailability after oral dosing than with IV injection (1:40 for propranolol). Volume of distribution for various beta-blockers generally exceeds 1 L/kg, meaning tissue concentrations exceed those of serum. Therefore, hemodialysis is not efficacious for most beta-blockers. Protein binding varies from 0% for sotalol to 93% for propranolol. Elimination half-lives vary from 8 to 9 minutes for esmolol to as long as 24 hours for nadolol and others (see Table 150-3).

**Clinical Features**

The most common initial sign remains bradycardia, which should draw attention to the possibility of cardiac drug overdose. Hypotension and unconsciousness are the second and third most common signs (Box 150-8). Much of propranolol’s toxicity derives from its lipophilic nature and membrane-stabilizing effect that allow it to penetrate the CNS, leading to obtundation, respiratory depression, and seizures. Other beta-blockers do not have these effects. Seizures probably result from a combination of hypotension, hypoglycemia, hypoxia, and direct CNS toxicity. Surprisingly, bronchospasm is not problematic in cases of beta-blocker overdose, even with nonselective beta-blockers. The few cases of symptomatic bronchospasm respond to the usual bronchodilator nebulizations.

Propranolol’s membrane-stabilizing effect impairs SA and AV node function and leads to bradycardia and AV block. Ventricular conduction is also depressed, leading to QRS widening and occasional ventricular dysrhythmias. Nadolol and acebutolol also have a significant membrane-stabilizing effect. These beta-blockers, like the tricyclic antidepressants, can cause ventricular dysrhythmias such as ventricular tachycardia, ventricular fibrillation, and torsades de pointes as well as the bradydysrhythmias more characteristic of beta-blockers in general. The intrinsic sympathomimetic activity of some beta-blockers such as pindolol and carteolol has led to some unusual manifestations such as sinus tachycardia instead of bradycardia and ventricular dysrhythmias. Labetalol is unique in that it also blocks alpha-adrenergic receptors, yielding an additional mechanism for hypotension. However, labetalol’s beta-blockade is three to seven times more potent than its alpha-

**MANIFESTATIONS AND COMPLICATIONS OF BETA-BLOCKER OVERDOSE IN ORDER OF DECREASING FREQUENCY**

1. Bradycardia (65/90 cases)
2. Hypotension (64/90)
3. Unconsciousness (50/90)
4. Respiratory arrest or insufficiency (34/90)
5. Hypoglycemia (uncommon in adults)
6. Seizures (common only with propranolol, 16/90)
7. Symptomatic bronchospasm (uncommon)
8. VT or VF (6/90)
9. Mild hyperkalemia (uncommon)
10. Hepatotoxicity, mesenteric ischemia, renal failure (rare or single case reports)

*Intoxication with beta-sympatholytics. VF, ventricular fibrillation; VT, ventricular tachycardia.
blockade.

In contrast to digitalis, beta-blocker toxicity has a more rapid onset: life-threatening CNS and cardiovascular effects can occur 30 minutes after oral overdose. Patients ingesting delayed-release preparations may remain asymptomatic for several hours, affording a valuable therapeutic window.

**Diagnostic Strategies**

Diagnosis and management depend on the clinical picture since blood levels of beta-blockers correlate poorly with severity of intoxication and are not readily available. Most urine toxicology screens do not identify antidysrhythmic drugs and are not helpful. Hypoglycemia is common in children, and bedside glucose determination should be done with obtundation. Known access of the patient to a beta-blocker and consistent clinical features such as obtundation, seizures, bradydysrhythmias, and occasionally tachydysrhythmias should lead the clinician to consider beta-blocker intoxication.

**Differential Considerations**

The combination of bradycardia and hypotension suggests beta-blockade or calcium channel blockade. Without a history of beta-blocker ingestion, the diagnosis can be challenging, especially when noncardiac effects such as CNS depression and seizures predominate. Sodium channel poisoning with QRS widening can occur, suggesting other antidysrhythmic drugs or cyclic antidepressants. The differential diagnosis also includes sedative-hypnotic drug overdose, hypoglycemic drug ingestion, opiate overdose, CNS injury or infection, endocrine-metabolic disorder, sepsis, and acute myocardial infarction.

**Management**

Immediate measures include IV fluids, supplemental oxygen, and monitoring of card for rhythm and respirations. Activated charcoal has been used in the first hour after overdose as a theoretical but unproven treatment. Similarly, multiple-dose charcoal (0.5 g/kg every 4 hr) has been recommended for beta-blockers that undergo enterohepatic or enteroenteric circulation, again without supporting evidence for an improvement in outcome. Specific management of dysrhythmias and hypotension should not be delayed by administration of charcoal. Evidence for improved outcome is also lacking but whole-bowel irrigation has been advocated for sustained-release preparations with a polyethylene glycol solution (OCL, GoLytely, CoLyte), administered orally or via nasogastric tube at 1 to 2 L/hour in adults or 20 mL/kg initially in children. With currently available evidence, gastric decontamination by activated charcoal or whole-bowel irrigation can neither be recommended nor criticized. Onset of toxicity is so uniformly early that absence of symptoms 4 hours after ingestion implies a low risk for subsequent morbidity unless a delayed-release preparation is involved.

**Hypotension, Bradycardia, and Atrioventricular Block**

Because bradycardia and heart block are usually attended by hypotension, catecholamines with chronotropic and dromotropic as well as inotropic and vasopressor effects should be chosen. Although therapeutic doses of beta-blockers may exacerbate Raynaud’s phenomenon through an unopposed alpha effect, extreme peripheral vasodilation is the rule in cases of overdose. It is rare for one catecholamine to be equally effective against all four toxic effects, so combinations of drugs are often used in severe cases.

The first step in the treatment of beta-blocker overdose is bolus administration of atropine, glucagon, and crystalloid fluids. A dose of atropine may quickly wear off or be ineffective, so infusion of more potent drugs or cardiac pacing is usually necessary. Atropine (0.5 mg for adults, 0.02 mg/kg for children, minimum 0.10 mg) should be given before vagal stimuli such as tracheal or gastric intubation. Glucagon, which does not depend on beta-receptors for its action, has both inotropic and chronotropic effects.

Furthermore, it helps to counteract the hypoglycemia induced by beta-blocker overdose. Glucagon is given as a 5- to 10-mg IV bolus. Because of its short (20-minute) half-life, an infusion of 2 to 5 mg/hr (or for children, 0.05–0.1 mg/kg bolus, then 0.05–0.1 mg/kg/hr) should be started immediately after the bolus. With cumulative large doses, glucagon should be diluted in 5% glucose in water for constant infusion. 

Side effects include nausea and vomiting in most patients, mild hyperglycemia, hypokalemia, and allergic reactions. The response to glucagon alone is often inadequate.

Sodium channel blockade, manifested by QRS widening, occasionally occurs with beta-blocker intoxication and may respond to infusion of sodium bicarbonate.

In hypotensive patients, 20 to 40 mL/kg of normal saline or Ringer’s lactate solution can be infused and repeated. If hypotension or bradycardia persists, other cardiovascular drugs are indicated. A single drug of choice after glucagon has not emerged, but many clinicians favor isoproterenol (isoprenaline in Europe), dopamine, or epinephrine. Other catecholamines that have been successfully used include norepinephrine, dobutamine, prenalaterol, metaraminol, and phenylephrine. Often, norepinephrine or dopamine is added to beta-agonists such as isoproterenol that lack vasopressor activity. Because patients are resistant to these drugs, the initial dose should be high and the infusion rates should be rapidly titrated to effect. A common mistake with cases of beta-blocker overdose is to timidly titrate catecholamine infusions within previously familiar ranges. In the setting of massive beta-blockade, much higher doses are usually needed, such as isoproterenol up to 200 μg/min, and the drug is titrated to effect.

High-dose (0.5–1 unit/kg/hr) insulin infusion for hemodynamically significant toxicity is often given before traditional pressors. Beta-blocker toxicity shifts myocardial energy preferences from free fatty acids to carbohydrates, and insulin increases myocardial carbohydrate uptake. Recent canine and porcine models showed the benefit of insulin infusion up to 10 units/kg/hr.

Glucose, usually in 5 to 10% solutions, is infused to maintain a serum glucose of approximately 100 mg/dL. The combination of glucose and high-dose insulin augments myocardial contraction independent of beta-receptors. Glucose and potassium should be monitored frequently during infusion and supplemented as needed to maintain euglycemia and eukalemia.

Refractory cases of bradycardia may respond to an external or transvenous pacemaker. Phosphodiesterase inhibitors such as aminophylline, amrinone, and milrinone have also been used as a final treatment to treat beta-blocker overdose in experimental animals and in humans. Like glucagon, they also help raise intracellular cyclic AMP levels and stimulate contractility.

**Calcium**

Because deleterious effects on calcium transport may contribute to beta-blocker toxicity, IV calcium salts have been suggested for treating hypotension. In animals, hypercalcemia as well as hypocalcemia can inhibit the action of glucagon, and until more is known, calcium should be given cautiously.
Ventricular Dysrhythmias

Although uncharacteristic, ventricular tachydysrhythmias do occur sometimes. Cardioversion and defibrillation are indicated for ventricular tachycardia and ventricular fibrillation, respectively, following American Heart Association guidelines. Pulsatile ventricular tachycardia or frequent ventricular ectopy can most safely be treated with lidocaine. Other antidysrhythmic drugs, especially of classes IA and IC, should be avoided because they may potentiate AV block or be prodrhythmic because of an additive membrane stabilizing effect. Sotalol, unlike other beta-blockers, has class III as well as class II effects; that is, it prolongs the QT interval and can cause torsades de pointes and other ventricular dysrhythmias. Overdrive pacing with isoproterenol or a pacemaker and magnesium sulfate are specific therapies for torsades de pointes.

Extracorporeal Elimination and Circulatory Assistance

Hemodialysis or hemoperfusion may be beneficial for atenolol, nadolol, sotalol, and timolol, the beta-blockers with lower $V_d$, lower protein binding, and greater hydrophilicity. Unlike overdoses of acetaminophen and iron, cardiovascular drugs do not destroy tissue, and if circulation can be supported, complete recovery can be expected. An intra-aortic balloon pump or cardiopulmonary bypass can be lifesaving in cases of refractory hypotension. The relatively short half-lives (hours rather than days) of beta-blocking and calcium-blocking drugs fall within the temporal range of such interventions. To be successful, such heroic measures must be taken before prolonged hypotension leads to multiorgan ischemic injury (Box 150-9). Because most patients recover with just supportive care, these expensive and invasive interventions should be reserved for drugs and circumstances, such as propranolol, verapamil, and mixed cardiotoxic overdoses, that are associated with higher rates of mortality.

Pediatric Considerations

Compared with adults, pediatric poisonings are rare. In the cases reported, CNS, cardiac, and metabolic toxicities are similar. However, symptomatic hypoglycemia is much more common in children, especially in those who have been fasting, and occurs even after therapeutic doses. Therefore, serum glucose concentration should be measured in children. Risk factors include young age, fasting state, and diabetes mellitus. Obtunded children should receive empirical glucose, 1 to 2 mL/kg of 25% glucose IV. Generally, 5% glucose infusions have been sufficient to maintain euglycemia, especially with concomitant use of glucagon and catecholamines, which stimulate glucose release. Because glucose mobilization is a beta$_2$ effect, hypoglycemia may be less common with the cardioselective (beta$_1$) blockers.

Seizures also occur in cases of pediatric beta-blocker overdose, but hypoglycemia is probably an important contributing factor. They are more common with the lipid-soluble beta-blockers propranolol and oxprenolol. Diazepam is effective.

Children generally fare well after beta-blocker ingestion with symptoms in only 8 of 378 (2%) potential beta-blocker exposures in children.

Disposition

Patients who remain completely asymptomatic for 6 hours after an oral overdose of normal-release preparations can be safely referred for psychiatric evaluation, with medical consultation for the first 24 hours. Patients ingesting sustained-release preparations should be admitted to a monitored bed, but those who remain asymptomatic 8 hours after ingestion are very unlikely to develop toxicity. Those who have been hypertensive, who have more than first-degree heart block, or who have hemodynamically significant dysrhythmias should be admitted to the intensive care unit.

CALCIUM CHANNEL BLOCKERS

Perspective

Verapamil and nifedipine, the earliest calcium channel antagonists, were introduced in Europe in the 1970s and in the United States in the early 1980s. Calcium antagonists have found many clinical applications: angina pectoris, hypertensive supraventricular dysrhythmias, hypertrophic cardiomyopathy, and migraine prophylaxis. Over 2000 cases of poisoning are reported annually to American poison centers. Most fatalities occur with verapamil, but severe toxicity and death have been reported for most drugs of this class.

Pathophysiology

Calcium channel antagonists block the slow calcium channels in the myocardium and vascular smooth muscle, leading to coronary and peripheral vasodilation. They also reduce cardiac contractility, depress SA nodal activity, and slow AV conduction. In cases of overdose, verapamil has the deadliest profile, combining severe myocardial depression and peripheral vasodilation. Both verapamil and diltiazem act on the heart and blood vessels, whereas nifedipine causes primarily vasodilation. As with beta-blockers, selectivity is lost in cases of overdose, and toxicity is fourfold, with negative effects on inotropy, chronotropy, dromotropy, and vasotropy.

All calcium channel blockers are rapidly absorbed, although first-pass hepatic metabolism significantly reduces bioavailability (Table 150-4). Onset of action and toxicity ranges from less than 30 minutes to 60 minutes, which has important implications for therapy. Peak effect of nifedipine can occur as early as 20 minutes after ingestion, but peak effect of sustained-release verapamil can be delayed for many hours. High protein

V_s, volume of distribution.

binding and V_s greater than 1 to 2 L/kg make hemodialysis or hemoperfusion ineffective. Fortunately (except with sustained-release preparations), their half-lives are relatively short, limiting toxicity to 24 to 36 hours.

Clinical Features

Severe calcium antagonism eventually affects multiple organ systems, but cardiovascular toxicity is primarily responsible for morbidity and mortality. Hypotension and bradycardia occur early, and other rhythm disturbances include AV block of all degrees, sinus arrest, AV dissociation, junctional rhythm, and asystole. Nifedipine overdose more commonly causes reflex sinus tachycardia from peripheral vasodilation. Calcium channel blockade has little effect on ventricular conduction, so QRS widening is not seen early on. Ventricular dysrhythmias are also uncommon except with bepridil, which has class I antidysrhythmic properties. This drug prolongs the QT interval in a dose-related fashion, and intervals greater than 520 msec are associated with increased risk of ventricular tachycardia, especially torsades de pointes (Box 150-10).

Diagnostic Strategies

Serum levels of calcium antagonists are not readily available, nor do urine toxicology screens reliably detect this class of drugs. Blood samples should be obtained for measurement of glucose and electrolytes (including calcium and magnesium). Hyperglycemia secondary to insulin inhibition occurs occasionally, but the elevation is usually mild (150–300 mg/L), is usually short-lived (<24 hr), and generally requires no treatment. A metabolic (lactic) acidosis occurs with hypotension and hypoperfusion.

An electrocardiogram should be promptly obtained, with special attention to atrial and ventricular rates and PR, QRS, and QT intervals. A prolonged QRS or QT interval suggests bepridil or a co-ingested cardiac toxin such as a tricyclic antidepressant.

Differential Considerations

Differential diagnosis is similar to that of beta-blocker cases. Until characteristic rhythm disturbances supervene, many other toxic, metabolic, traumatic, and cardiovascular disorders can cause hypotension but less commonly cause bradycardia. Like the beta-blockers, calcium antagonists cause early toxicity, and symptoms can be expected within 6 hours of ingestion of normal-release preparations. Toxicity can be delayed 12 to 24 hours with sustained-release preparations.

As with beta-blockade, CNS-depressive effects are common and include lethargy, confusion, and coma. Unlike beta-blockers, calcium antagonists seldom induce seizures. Pulmonary effects include noncardiogenic pulmonary edema and apnea can also occur. As with digitalis and beta-blocker overdose, nausea and vomiting are common.

Management

Initial management includes rapid establishment of vascular access, supplemental oxygen, cardiac monitoring, and frequent blood pressure measurement. Because of the rapid onset of toxicity with normal-release preparations, gastric emptying is dangerous and contraindicated. Vomiting is a powerful vagal stimulus that can exacerbate bradycardia and heart block. There is no evidence for improved outcome with activated charcoal. If activated charcoal use is contemplated despite this, it should be reserved for very early (<1 hr) presentations, or poisoning by a delayed-release preparation. Sorbitol should be avoided because hypotension frequently causes an ileus where residual sorbitol is metabolized to cause abdominal distension.

Manifestations and Complications of Calcium Channel Blocker Poisoning

**Cardiovascular:** Hypotension, sinus bradycardia, sinus arrest, AV block, AV dissociation, junctional rhythm, asystole; ventricular dysrhythmias uncommon except with bepridil

**Pulmonary:** Respiratory depression, apnea; pulmonary edema; adult respiratory distress syndrome

**Gastrointestinal:** Nausea, vomiting, bowel infarction (rare)

**Neurologic:** Lethargy, confusion, slurred speech, coma; seizures (uncommon); cerebral infarction (rare)

**Metabolic:** Metabolic (lactic) acidosis; hyperglycemia (mild); hyperkalemia (mild)

**Dermatologic:** Flushing, diaphoresis, pallor, peripheral cyanosis

AV, atrioventricular.
Hypotension can be caused by myocardial depression, inadequate heart rate, or peripheral vasodilation. Atropine can be administered in the usual American Heart Association’s recommended doses (0.5–1 mg, up to 3 mg for adults, and 0.02 mg/kg for children, minimum 0.1 mg). Atropine’s effect has often been disappointing and short-lived, and multiple doses risk anticholinergic poisoning. If symptomatic bradycardia or heart block persists, the next step is a pacemaker or chronotrope such as isoproterenol. A bolus of crystalloid fluid (20 mL/kg or more) should also be infused early. Intravenous calcium salts have traditionally been given to most patients. Their effect on contractility is considerable, but their effect on bradycardia, AV block, and peripheral vasodilation is often poor. The optimal dose of calcium is unknown. A reasonable dose is 6 g of calcium chloride, but some have given much higher calcium infusions, administering up to 30 g and raising the total serum calcium level to as high as 23.8 mg/dL.

Adverse effects of hypercalcemia include lethargy, coma, anorexia, nausea, vomiting, pancreatitis, polyuria, dehydration, and nephrocalcinosis. Most of these effects have been reported after weeks or months of hypercalcemia from malignancy or hyperparathyroidism. It is doubtful that hours or days of acutely induced hypercalcemia would be detrimental in the setting of massive calcium channel blockade. However, with rapid IV injection in animals and humans, bradycardia, AV block, AV dissociation, junctional tachycardia, ventricular ectopy, and ventricular fibrillation have been reported.

Extravasation of calcium salts can cause severe tissue necrosis. Administration through a central venous catheter is safer than through a peripheral IV line. Infiltration of calcium gluconate is less destructive than calcium chloride, but larger doses are necessary because it provides fewer calcium ions.

It is prudent to raise the total serum calcium level no higher than 14 mg/dL, which the endocrine and oncology literature define as the threshold of “severe” hypercalcemia. If ionized calcium levels are followed, it is probably wise not to exceed twice-normal levels. Adults should receive 10 to 20 mL of 10% calcium chloride slowly over 5 to 10 minutes, followed by a constant infusion of 5 to 10 mL/hour. Children can receive 10 to 30 mg/kg (0.1–0.3 mL/kg) of 10% calcium chloride initially. The serum calcium level can be as high as 18.2 mg/dL within 15 minutes after a bolus of just 5 mL of 10% calcium chloride, so levels should be measured later during the constant infusion.

As with beta-blocker poisoning, a monotherapeutic approach will probably succeed only for trivial overdoses. Most severely poisoned patients require addition of catecholamines to accelerate the heart rate (chronotropy), enhance AV conduction (dromotropy), and restore tone to peripheral vessels (vasotropy). Most experience and success have been reported with isoproterenol and dopamine, often in combination. Isoproterenol infusion can begin at 2 to 10 µg/min (0.1 µg/kg/min in children), but much higher rates may be needed. Unlike beta-blocker overdose, however, the beta-adrenergic receptor remains intact, and lower catecholamine infusion rates have generally been effective (e.g., dopamine 5–30 µg/kg/min). Epinephrine, norepinephrine, and dobutamine have also led to successful outcomes. Isoproterenol or dobutamine alone may not reverse or may even exacerbate peripheral vasodilatation; therefore, it is logical to add a vasopressor such as norepinephrine, metaraminol, phenylephrine, or high-dose dopamine.

Glucagon has also been used for its inotropic and chronotropic effects, in doses similar to those advocated for beta-blocker poisoning. Bailey recently reviewed 30 controlled animal studies (no controlled human studies exist) of glucagon use in beta-blocker and calcium channel blocker overdose.
Hyperglycemia occasionally occurs in children, but the elevation is usually short-lived. Although insulin has been administered in a handful of cases, it is generally not necessary, because the hyperglycemia usually resolves spontaneously within 24 to 36 hours.

A small number of children in refractory shock secondary to drug toxicity have been treated with intra-aortic balloon counterpulsation or cardiac bypass. For a toxin with a reasonably short half-life, although lethal, it does not directly cause irreversible tissue damage. Circulatory support during the day or two required for hepatic or renal elimination of the drug is potentially beneficial. In summary, aside from the differences previously noted, the presentation in children is similar to that in adults: rapid onset of toxicity with CNS depression, bradydysrhythmias, hypotension, and metabolic acidosis.

Disposition

Because the peak effect of normal-release calcium channel blockers commonly occurs in 90 minutes to 6 hours, patients who are totally asymptomatic for 6 hours after an ingestion can be safely discharged according to psychiatric needs. Symptomatic patients or those who ingested delayed-release preparations should be admitted to a medical or toxicology service for at least 24 hours of continuous cardiac monitoring.

Nitrates and Nitrites

Nitrates (nitroglycerin, isosorbide mono- and dinitrate) are widely used as vasodilators in the treatment of heart failure and ischemic heart disease. They augment coronary blood flow as well as reduce myocardial oxygen consumption by reducing afterload. At lower doses nitrates primarily dilate veins, but at higher doses they also dilate arteries. Hypotension is a common complication, but usually responds to supine positioning, IV fluids, and reduction of dose. Hypotension is usually transient. Low-dose pressors are occasionally needed, but it is best to avoid them in the setting of acute coronary syndromes.

Intravenous nitroglycerin infusions are being used commonly in patients with acute pulmonary edema for afterload reduction. Infusions are usually initiated at 5 to 10 µg/min, but rates as high as 200 to 300 µg/min may be used. These doses may be beneficial in patients with pulmonary edema accompanied by acute hypertension, but hypotension may develop suddenly. Intravenous nitroglycerin has a rapid offset of action, so excessive fall in blood pressure usually responds to reducing or terminating the infusion. Use of nitrates is contraindicated in patients who have recently taken sildenafil (Viagra). Sildenafil and related drugs (vardenafil/Levitra and tadalafl/Cialis) inhibit type-5 phosphodiesterase, thereby relaxing vascular smooth muscle. These agents can prolong and intensify the vasodilating effects of nitrates, resulting in severe hypotension. If blood pressure does not rise with IV fluids, dopamine should be cautiously titrated, beginning at 5 µg/kg/min.

Nitrates are occasionally found in rural well water contaminated by livestock or fertilizer runoff. Oral nitrates may be converted to nitrates in the gastrointestinal tract, especially in infants, whose hemoglobin is also more susceptible to oxidation. However, most exposures are encountered in young adults, usually male, who inhale various alkyl nitrates (amyl, butyl, isobutyl, or ethyl nitrite) in the hope of enhancing or prolonging sexual pleasure. Because of the sound they make when broken open, these products are best known to abusers as “poppers.” The popularity of poppers has waned in recent years as sales of sildenafil and related products have soared.

Nitrites and nitrates are both potent vasodilators, and excessive use can cause headache, skin flushing, and orthostatic hypotension. Nitrites are also oxidizing agents that convert hemoglobin to methemoglobin, impairing oxygen delivery. Though most exposure is by inhalation, unintentional ingestion may occur, because nitrites are also used legitimately as food preservatives. A family of five developed methemoglobinemia after consuming a meal seasoned with sodium nitrite mislabeled as table salt.

Patients with glucose-6-phosphate dehydrogenase deficiency are especially susceptible to the oxidative stress of nitrite exposure, and they may even develop hemolysis. When methemoglobin levels exceed 15%, a venous blood sample appears chocolate brown, and the skin appears blue even while patients look remarkably comfortable. Unlike most cases of cyanosis, supplemental oxygen does not improve the patient’s color. Pulse oximetry is not reliable, and the partial pressure of oxygen remains normal in mild to moderate cases. This rare complication can be treated with IV methylene blue, but this antidote is usually not needed unless methemoglobinemia approaches 30% or the patient develops more reliable signs of distress, such as tachypnea, tachycardia, acidosis, and hypotension. The usual dose of methylene blue in adults is 1 to 2 mg IV over 5 minutes.

CHAPTER 151  Caustics

Paul M. Wax and Amy Young

PERSPECTIVE

Caustic or corrosive agents have the potential to cause tissue injury on contact with mucosal surfaces. Agents capable of causing chemical injury include alkaline and acidic corrosives. Alkalis accept protons, resulting in the formation of conjugate acids and free hydroxide ions. Lye is an example of an alkali caustic and refers to both sodium hydroxide (NaOH) and potassium hydroxide (KOH). Ammonia (NH₃) is another common alkaline corrosive. Acids are proton donors, as they dissociate into conjugate bases and free hydrogen ions in solution. Acidic caustics include hydrochloric acid (HCl) and sulfuric acid (H₂SO₄). The severity of caustic agents typically increases with a pH less than 3 or greater than 11. On the contrary, hydrofluoric acid (HF) is a relatively weak acid that can cause necrotizing injury and life-threatening systemic toxicity. Other chemicals that have caustic properties include phenol, formaldehyde, iodine, and concentrated hydrogen peroxide. This chapter discusses oral exposure. Dermal and inhalational exposures are discussed in Chapter 61 and Chapter 157, respectively.

Caustic exposures are either intentional suicidal ingestions or accidental ingestions in the pediatric and elderly populations. At least 85% of reported caustic ingestions are unintentional. Transfer and storage of cleaners in alternative containers, such as soda bottles and jars, contribute to unintentional ingestion. Intentional ingestions have a greater degree of oropharyngeal sparing due to rapid swallowing but have a higher likelihood of serious injury. More than half of suicidal patients who ingest caustic agents have a history of psychiatric illness. Prior to 1950, strong lye with concentrations greater than 50% made up a major portion of caustic ingestions in the United States leading to poor outcomes. To control the frequency of caustic ingestions especially in children, the Federal Caustic Act was passed in 1927 followed by the Federal Hazardous Substance Labeling Act of 1960 and the Safe Packaging Act of 1970. Still, over 45,000 exposures involving caustic agents still occur in the United States every year.

Presently, some household products such as liquid drain cleaners continue to have high concentrations of alkali (30% KOH) or acid (93% H₂SO₄) (Table 151-1). Commercial industries, farms (dairy pipeline cleaners containing liquid NaOH and KOH in concentrations of 8–25%), and swimming pool chemicals also contain caustics in high concentrations.

Ingestion of crystals and solid particles can have prolonged tissue adherence, causing more severe burns. These ingestions are limited by immediate oral pain, usually causing them to be spit out sooner than a liquid agent. The ingestion of granular automatic dishwashing detergents is associated with devastating injury. Crystal drain cleaners have lye concentration as high as 74% NaOH and may cause proximal esophageal injury. Liquid dishwashing detergents and laundry detergents have a pH greater than 12, but because the titratable base content is significantly less, there is less risk of injury after ingestion.

Liquid household bleach contains dilute (5.25%) sodium hypochlorite (NaHClO), and ingestion rarely causes injury. Industrial-strength bleach may contain significantly higher concentrations of NaHClO, leading to esophageal necrosis. Toilet bowl cleaners contain hydrochloric acid as high as 26% HCl. General-purpose anticorrosive cleaners, such as 31% muriatic acid (HCl), are sold in gallon containers for home use and as swimming pool cleaners.

The alkali powder in air bags can cause ocular burns. Perfume accidentally sprayed into the eyes can be caustic. Cement is alkaline and causes topical burns, typically on the knees. Although hair relaxer creams contain NaOH and have a pH of 11.2 to 11.9, injuries after ingestion are usually limited.

Caustic ingestions may occur when methamphetamine is produced from over-the-counter medications and household chemicals. Sulfuric acid, hydrochloric acid, NaOH, ammonium hydroxide, anhydrous ammonia, and metallic lithium are all used in the clandestine production of methamphetamine. Severe caustic injuries in these situations can cause stricture formation, esophageal resection, and the need for colonic interposition.

More than 70 different pills can cause damage when they come in contact with esophageal mucus for prolonged periods. Patients who take medications in the supine position, or who take pills without water, are at higher risk. Pills most likely to adhere are doxycycline, tetracycline, potassium chloride, and aspirin. Potassium chloride is particularly dangerous and has caused perforation into the aorta, left atrium, and bronchial artery.

PRINCIPLES

Factors that influence the extent of injury from a caustic exposure include type of agent, concentration of solution, volume, viscosity, duration of contact, pH, and presence or absence of food in the stomach. The titratable alkaline reserve of an alkali or acid correlates with the ability to produce tissue damage.
Concentrated forms of acids and bases generate heat resulting in superimposed thermal injury. Acidic compounds desiccate epithelial cells and cause coagulation necrosis. An eschar is formed thereby limiting further penetration. Because acids tend to have a strong odor and cause immediate pain on contact, the quantity ingested is usually limited. Because of resistance of squamous epithelium to coagulation necrosis, acids are thought to be less likely to cause esophageal and pharyngeal injury, although severe esophageal and laryngeal burns may still occur. Acids can be absorbed systemically, causing metabolic acidosis, as well as damage to the spleen, liver, biliary tract, pancreas, and kidneys.

Alkaline contact causes liquefaction necrosis, fat saponification, and protein disruption, allowing further penetrance of the alkaline substance into the tissue. The depth of the necrosis depends on the concentration of the lye. A concentration of 30% NaOH in contact with tissue for 1 second results in a full-thickness burn. Alkalis are colorless, odorless, and unlike acids, do not cause immediate pain on contact. Alkaline ingestions typically involve the squamous epithelial cells of the oropharynx, hypopharynx, and esophagus. The narrow portions of the esophagus, where pooling of secretions can occur, are also commonly involved. Alkalis may also cause gastric necrosis (Figs. 151-1 and 151-2) and perforation. The esophagus can also be injured (Fig. 151-3). Burns below the pylorus carry a worse prognosis than burns above the pyloris (50% vs. 9% mortality).

Classically, the damage occurs in four steps. Initially, necrosis occurs, with invasion by bacteria and polymorphonuclear leukocytes. Vascular thrombosis follows, increasing the
damage. Over the next 2 to 5 days, superficial layers of injured tissue begin to slough. The tensile strength of the healing tissue may be quite low for up to 3 weeks following the caustic exposure, greatly increasing the chance of delayed perforation in some cases. Between 1 week and several months, granulation tissue forms, collagen is deposited, and a re-epithelization occurs in the burn area. Esophageal stricture may form over a period of weeks to years from contraction of the scar.

Caustic injury is categorized as first-, second-, and third-degree, similar to a thermal burn, based on appearance at endoscopy. The initial depth of injury found on esophagoscopy correlates with the risk of stricture formation. First-degree burns (also known as grade 1) consist of edema and hyperemia. Second-degree burns (grade 2) can be further divided into 2a, which are noncircumferential, and 2b, which are near-circumferential. Overall, second-degree burns are characterized by superficial ulcers, whitish membranes, exudates, friability, and hemorrhage. Third-degree burns (grade 3) are associated with transmural involvement with deep injury, necrotic mucosa, or frank perforation of the stomach or esophagus. Although grade 1 injuries do not progress to stricture, 15 to 30% of all grade 2 burns and up to 75% of circumferential grade 2 injuries of the esophagus develop strictures. With full-thickness third-degree burns (grade 3), 90% result in stricture. Whether heat from the exothermic reaction increases the injury has never been quantified, but it has led to concerns regarding initial dilution or gastric lavage.

**CLINICAL FEATURES**

Airway edema and esophageal/gastric perforation are the most emergent issues. Laryngeal edema occurs over a matter of minutes to hours. Systemic toxicity; hypovolemic shock; and hemodynamic instability with hypotension, tachycardia, fever, and acidosis are ominous findings. Small ingestions of potent substances can be as serious as larger ingestions. More than 40% of patients reporting to have “only taken a lick” have esophageal burns. Patients present with oral pain (41%), abdominal pain (34%), vomiting (19%), and drooling (19%). Many patients have wheezing and coughing. Others present with stridor and dysphonia. Chest pain is common. Visible burns to the face, lips, and oral cavity may be seen (Fig. 151-4). Skin burns can occur from spillage or secondary contamination after vomiting. Peritoneal signs suggest hollow viscous perforation or contiguous extension of the burn injury to adjoining visceral areas. Tracheal necrosis is one of the most frequent causes of death after caustic ingestion.

Studies present conflicting data correlating clinical symptoms with the severity of esophageal burns. Oropharyngeal burns alone do not appear predictive of more distal injury, but prolonged drooling and dysphagia predicted significant lesions with 100% sensitivity and 90% specificity. Vomiting and stridor may also be more predictive of burn injury. Dysphagia usually subsides in 3 to 4 days. Patients with significant esophageal burns, particularly those that are circumferential, may develop esophageal stricture; 80% of strictures become apparent in 2 to 8 weeks. Symptoms include dysphagia and food impactions. Strictures that become symptomatic early are generally more severe. In one study of 86 adults admitted to the hospital after caustic ingestion, 18 developed complications and 6 died.

Patients have an increase in esophageal cancer (1000-fold to 3000-fold increases) that develops 40 to 50 years after the caustic ingestion. A recent long-term study showed that 1.8% of patients who ingested caustic soda developed esophageal cancer. Nearly 3% of esophageal cancer patients have a history of caustic ingestion.

Significant acid ingestions may be devastating and result in a higher mortality rate than alkali ingestions. The fulminant course of some acid ingestions may be due to systemic absorption of the acid, resulting in metabolic acidosis (which may also be the result of extensive tissue necrosis), hemolysis, and renal failure. In Russia, concentrated acetic acid ingestions account for 64% of caustic ingestions.

**DIAGNOSTIC STRATEGIES**

The goal is to identify the extent and severity of the burn. Patients with chest and abdominal pain should have a chest radiograph and decubitus or upright abdominal studies to identify peritoneal and mediastinal air, denoting perforation or pleural effusion. Any suggestion of abdominal involvement should prompt abdominal computed tomography or ultrasonography. Arterial blood gas determination may be useful after significant acid ingestions to monitor systemic metabolic acidosis. In cases of intentional overdose, co-ingestants should be considered.

Hydrofluoric acid exposures, whether inhalational, ingestion, or dermal (hand size or larger), require immediate cardiac monitoring to assess for QT, prolongation, torsades de pointes, or other ventricular dysrhythmias. Rapid cardiac deterioration should be expected in these unusual cases. Serum calcium and magnesium levels should also be determined, but empirical intervention with high-dose intravenous calcium chloride may be required for life-threatening dysrhythmias before confirmatory laboratory data are available.

The depth of burns cannot be predicted based on signs or symptoms. Noninvasive techniques (barium swallow) do not gauge the depth of burn injury. Endoscopy is contraindicated in patients with possible or known perforation. The finding of frank necrosis or obliteration of the lumen should result in termination of the endoscopic procedure. Patients with signs and symptoms (vomiting, drooling, stridor, or dyspnea) of intentional ingestion should undergo endoscopy within 12 to 24 hours to define the extent of the disease. Endoscopy performed too early may miss the extent or depth of tissue injury. Wound softening in the subacute phase when the likelihood of perforation is greatest makes late endoscopy (after 24 hours) more hazardous. A soft feeding tube or silk string can be placed in the esophagus, when burns are present, for future dilation. With the current flexible endoscopes, endoscopy should be continued past the area of burn and into the stomach, if possible.
Patients can be divided into four groups based on the results of endoscopy: (1) no esophageal/gastric injury, (2) gastric injury, (3) linear burns of the esophagus, and (4) circumferential burns.

**MANAGEMENT**

After a caustic ingestion, little can be done to attenuate the severity of the tissue injury. In evaluating a patient, the patient's history should include the time, amount, type of product ingested, and presence of suicidal ideations if any. Product labels are important in confirming the concentration of the chemical. If a sample is obtained, test the pH with litmus paper.

Early endotracheal intubation is warranted when airway compromise is suggested by hoarseness, throat pain, drooling, or edema. Intubation should also be undertaken early if significant exposure is suggested, before edema and secretions both threaten the airway and make intubation difficult or impossible. Blind nasotracheal intubation is contraindicated. When oral intubation is anticipated to be difficult or impossible because of edema and anatomic distortion, rapid-sequence intubation should be avoided and awake fiberoptic intubation or primary surgical cricothyrotomy may be necessary (see Chapter 1).

Patients who are suicidal may minimize their symptoms or have symptoms that understate the trauma. Intubation may not be enough to secure the airway. Hypoxia and an increased arterial-alveolar gradient warrant immediate bronchoscopy. In the suicidal patient, the physical examination and chest radiograph do not “rule out” pneumoperitoneum. Radiographs have low negative predictive values for detecting free air.

Patients should have intravenous access and vigorous fluid resuscitation. In alert patients who are not vomiting and can tolerate liquids, small volumes (1–2 cups) of water or milk can be considered within the first few minutes after ingestion. Because injuries occur almost immediately, later dilution is not warranted. Forcing fluids is never indicated. Likewise, do not neutralize the ingested corrosive with weak acids or alkalis due to possible thermal reactions and worsening injury.

Inducing emesis, administering activated charcoal, and performing gastric lavage are not indicated. Careful nasogastric aspiration may be useful in the setting of significant acid ingestions presenting immediately after the event, given the ominous natural history of many of these cases and the somewhat lower risk of esophageal perforation compared with alkali ingestion.

Immediate surgical exploration is indicated for free air, peritonitis, increasing and severe chest and abdominal pain, and hypotension. Early and continuous hemodynamic monitoring is essential. The patient should be fully examined for evidence of dermal and ocular caustic exposures. Contaminated clothing should be treated as hazardous waste and disposed of using proper precautions.

Corticosteroid therapy remains controversial. Its use had been previously advocated to potentially prevent stricture formation. The use of systemic corticosteroids in corrosive esophageal burns does not seem to be beneficial. They can be harmful in perforation because they mask early signs of inflammation and inhibit resistance to infection. Prophylactic antibiotics may potentially mask evidence of impending perforation.

Children in developing countries often present late, sometimes months later, with a well-established stricture. These strictures are difficult to dilate and at risk for perforation. Recurrent strictures and repetitive dilatation treatment is expected.

**DISPOSITION**

Surgical intervention is required in cases of hollow viscus perforation; early exploration may also be warranted in cases of suggested full-thickness burns. Asymptomatic patients can undergo endoscopy in the emergency department or be discharged home with close follow-up monitoring. Children with a questionable history of ingestion should be observed even if they are asymptomatic and have no oropharyngeal burns. They can have a liquid diet. Symptomatic patients particularly those with potential for airway compromise require admission to the intensive care unit. If endoscopy is unavailable, the patient should be transferred to a facility where it can be performed. Psychiatric evaluation is indicated in patients with intentional or possibly intentional ingestion.

**SPECIAL CASES**

Ocular alkali exposures are true ophthalmologic emergencies. Immediate and aggressive lavage with at least 2 L of normal saline per eye is indicated in all cases except for frank perforation. Management is described in Chapter 61.

Dermal caustic exposures can also result in significant burn injuries (see Chapter 60). Clothing removal, copious irrigation, and local wound débridement are the most important initial treatment measures. Hydrofluoric acid burns warrant special attention. Although this is a relatively weak acid compared with HCl or H2SO4, the dissociated fluoride anion is problematic because of its extreme electronegativity. Deaths from HF, exposure have occurred after ingestion, after skin contact in areas as small as 1% of the body surface area, with concentrated HF, and after inhalation of HF vapor. Systemic toxicity is characterized by immediate and profound hypocalcemia and dysrythmias; cardiac monitoring and serum calcium monitoring are warranted in all but the most limited fingertip exposures.

Povidone-iodine (Betadine) is used as a surgical scrub and is not a caustic agent, but ingestion of tincture of iodine can cause severe gastrointestinal injury and is potentially lifethreatening. Gastric irrigation with starch or milk in these cases may convert iodine to the much less toxic iodide.

Ingestion of phenol or formaldehyde can also cause epigastic pain to the gastrointestinal tract. Both phenol and formaldehyde are general protoplasmic poisons and can cause protein denaturation and coagulation necrosis. Systemic symptoms, including dysrythmias, hypotension, seizures, and coma, may also result from phenol ingestion. Acidosis may be quite prominent after formaldehyde ingestion due to its metabolism to formic acid. Phenol is well absorbed through the skin, and dermal exposure may result in burns and systemic toxicity. Although dermal decontamination of phenol exposures with low-molecular-weight polyethylene glycol has been suggested, irrigation with water may prove just as useful.

Ingestion of concentrated hydrogen peroxide (H2O2) may cause gastrointestinal burn injury and the formation of gas emboli. Radiographic evaluation for the presence of gas in the chest or abdominal cavities, including the portal system, should be performed in symptomatic patients or those who ingest concentrated H2O2. Hyperbaric oxygen has been used successfully to treat gas emboli from H2O2 ingestion.

Button (disk) batteries and conventional alkaline cylindrical batteries pose potential obstructive and chemical hazards if ingested. Ingestion of large 25-mm wafer-sized button batteries was a problem in the past but the smaller button batteries of today are less likely to cause esophageal obstruction. Button
batteries are usually made of a metallic salt (lithium, mercury, nickel, zinc, cadmium, or silver) bathed in NaOH or KOH. Obstruction can cause pressure necrosis, caustic injury due to leakage of alkaline medium, or electrical injury. Ulceration, perforation, and possible fistula formation occur but are uncommon. Heavy-metal toxicity in this setting has not been reported.\(^4\)\(^3\)

Evaluation of button battery ingestions requires radiography to assess the position of the foreign body. Batteries lodged in the airway or esophagus require expeditious removal. Gastric or intestinal batteries can be treated with watchful waiting.\(^4\)\(^3\) Checking the stool for passage of the batteries is recommended. Follow-up radiographs should be obtained in 1 week if the battery has not passed.

**KEY CONCEPTS**

- Ingestion of very small amounts of a caustic material (even a lick) can cause serious esophageal injury.
- All symptomatic patients should undergo endoscopy and be considered for admission.
- Asymptomatic patients can undergo endoscopy in the emergency department or be discharged with very close follow-up monitoring.
- Caustic ingestions can lead to esophageal stricture and a lifelong increased risk of esophageal cancer.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Cocaine, a naturally occurring plant-derived alkaloid, has been used for centuries as a medicinal product. For thousands of years in South America, the leaves of the cocoa plant (*Erythroxylon coca*) have been chewed for treatment of various ailments. In 1860, the pure alkaloid form was isolated and became a popular constituent of various beverages, pharmaceuticals, and therapeutic tonic but was banned from these products in 1914. At the peak of the cocaine epidemic in the early 1990s, it was estimated that 5 million people used cocaine regularly in the United States. The drug is still popular, and the consequences of recreational cocaine use are profound. Between 1993 and 1995, 2000 unintentional cocaine-related deaths were reported in New York City. Cocaine is also implicated in violent deaths and was detected in 25% of autopsies of fatal injuries in adults aged 15 to 44. In 2003, 39% of drug misuse deaths were due to cocaine.

Amphetamines are stimulants originally designed for use as decongestants and dietary aids that became popular as recreational drugs in the mid-20th century. Modifications of the amphetamine molecule, or illicit “designer” amphetamines, are inexpensively produced. The enhanced effects from these alterations add to the popularity of drugs such as 3,4-methylenedioxymethamphetamine (MDMA) and methamphetamines. Cocaine, amphetamines, and derivatives of amphetamines are called sympathomimetics (Box 152-1). These agents cause central nervous system (CNS) stimulation and a cascade of physiologic effects.

**Pathophysiology of Cocaine**

Acute cocaine use causes release of dopamine, epinephrine, norepinephrine, and serotonin. These neurotransmitters act on different receptor subtypes to cause many effects, but the most important are adrenergic stimulation by norepinephrine and epinephrine (see Box 152-1). Norepinephrine causes vasoconstriction by stimulating alpha-adrenergic receptors on vascular smooth muscle. Epinephrine increases myocardial contractility and heart rate through stimulation of beta-adrenergic receptors. In addition to causing catecholamine release, the reuptake of these stimulatory neurotransmitters from synaptic clefts is inhibited, altering the normal balance between excitatory and inhibitory tone in the CNS. Subsequent stimulation propagates peripheral catecholamine release (Fig. 152-1).

Cocaine also is a local anesthetic agent, slowing nerve impulses from neuronal pain fibers by blocking the inward movement of sodium across cell membranes (phase 0 of the action potential). Sodium channel blockade across myocardial cells, similar to the class IA antidyssrhythmic agents, is responsible for the occasional conduction abnormality with acute cocaine toxicity.

Cocaine metabolism occurs in the liver and the plasma. In the liver, the drug is metabolized primarily to the active metabolite norcocaine, which potentiates the parent drug. In the plasma, cocaine is metabolized to ecgonine methyl ester via pseudocholinesterase (plasma cholinesterase). This difference may account for the differences in duration of action with different routes of administration. Ecgonine methyl ester may be protective because it is a vasodilator. Genetic differences in the phenotypic expression of plasma cholinesterases may account for individual differences in susceptibility to cocaine toxicity.

Benzoyl ecgonine is a nonenzymatic metabolite found in the plasma and is the metabolite identified by urine toxicology screens. Methylecgonidine and its metabolite ecgonidine are products of cocaine pyrolysis (crack). Although less commonly assayed, methylecgonidine also can be identified in the urine. The use of ethanol with cocaine may form cocacethylene, a metabolite that may potentiate the drug’s stimulatory effects.

**Cocaine Formulations**

Unpurified cocaine paste is converted to usable forms of cocaine. The crystallized freebase of the cocaine alkaloid is known as “crack cocaine.” It is inhaled using a special “crack pipe” designed to tolerate the high temperature required to volatilize pure cocaine. The high lipid solubility and rapid transport from the lungs into the brain contribute to crack’s rapid onset of action (Table 152-1). The water-soluble salts of cocaine (cocaine hydrochloride and cocaine sulfate) are available as a white crystalline powder that is taken intranasally or dissolved and injected intravenously. Oral administration is rare except for patients who are smuggling or concealing drugs.
Chapter 152: / Cocaine and Other Sympathomimetics

Mortality from acute cocaine overdose is significantly higher on days with ambient temperatures greater than 88° F. The profound diaphoresis associated with cocaine may be absent or limited in cooler environments or if the patient is excessively dehydrated.

Initial assessment and treatment should focus on rapidly fatal complications, specifically hyperthermia, hypertensive emergencies, and cardiac dysrhythmias.

Hyperthermia

Acute psychomotor agitation with delirium increases the risk of hyperthermia. Intoxicated patients have increased motor tone and generate heat. Vasoconstriction and dehydration can compromise cooling, resulting in life-threatening hyperthermia with core temperatures exceeding 106° F (41.1° C). Delay in recognition and management may increase the likelihood of death. Even with a normal temperature, increased motor tone can release intramuscular creatine kinase (CK) with rhabdomyolysis and its attendant renal and electrolyte complications.

Hypertensive Emergencies

Acute cocaine-induced hypertension can seriously injure the cardiovascular system and CNS (see Chapter 83). Reported hypotension, hyperthermia, tachycardia, mydriasis, and hypertension without organ damage. A more severely intoxicated patient may present agitated, combative, and hyperthermic. Signs and symptoms of end-organ damage may be present, including acute hypertensive emergencies. Patients may present with focal, acute pain syndromes; circulatory abnormalities; delirium; or seizures.

The clinical presentation depends on the dose, route of administration, and time to presentation after drug use. Additives, contaminants, or other drugs may alter the classic signs of acute cocaine intoxication. Patients who are “speedballing,” using intravenous (IV) heroin and cocaine together, may be initially sedated, and administration of naloxone may precipitously reveal the underlying cocaine intoxication.

Mortality from acute cocaine overdose is significantly higher on days with ambient temperatures greater than 88° F. The profound diaphoresis associated with cocaine may be absent or limited in cooler environments or if the patient is excessively dehydrated.

Initial assessment and treatment should focus on rapidly fatal complications, specifically hyperthermia, hypertensive emergencies, and cardiac dysrhythmias.

Hyperthermia

Acute psychomotor agitation with delirium increases the risk of hyperthermia. Intoxicated patients have increased motor tone and generate heat. Vasoconstriction and dehydration can compromise cooling, resulting in life-threatening hyperthermia with core temperatures exceeding 106° F (41.1° C). Delay in recognition and management may increase the likelihood of death. Even with a normal temperature, increased motor tone can release intramuscular creatine kinase (CK) with rhabdomyolysis and its attendant renal and electrolyte complications.
Cardiac Dysrhythmias

A life-threatening dysrhythmia may not be noted until cardiac output abruptly diminishes, and the patient suddenly loses consciousness. Although sinus tachycardia is most common, atrial fibrillation and other supraventricular tachycardias can occur as a result of the surge in catecholamines. Torsades de pointes or wide-complex tachycardias from blockade of fast sodium channels on the myocardium may deteriorate into poorly perfusing or fatal ventricular rhythms. Transient conduction abnormalities consistent with a Brugada-type pattern have been associated with cocaine. Hyperkalemia from rhabdomyolysis and myocardial ischemia can also cause dysrhythmias.

Other Complications

People who binge with continuous use over an extended time have a prolonged state of arousal, which causes catecholamine depletion, dehydration, and poor nutrition. After the acute effects of cocaine have subsided, these patients with “cocaine washout” are profoundly sleepy but arousable and oriented, with normal vital signs or a mild sinus bradycardia.

Occasionally a patient has “crack dancing,” a transient choreoathetoid movement disorder probably related to abnormalities in dopaminergic tone. Deep vein thrombosis is reported with cocaine use, probably secondary to effects on coagulation. Paranoia, either drug-induced or from underlying psychiatric illness, may occur even after the acute effects of the drug subside. The neuropsychiatric effects of cocaine can alter behavior and judgment, increasing the risk of violent injuries.

Complications arise from the route of administration of cocaine. Inhalation of crack cocaine may cause oropharyngeal burns from the high temperature required to volatilize the drug. Pneumo- thorax, pneumopericardium, and pneumomediastinum occur from inhalational barotrauma. Intranasal cocaine use is associated with sinusitis and nasopalatine necrosis or perforation. Intravenous users have a high risk of infection with blood-borne viruses, local abscesses, and systemic bacterial infections, including botulism, and endocarditis. Transdermal injection of cocaine, or “skin popping,” has similar types of complications. For a chronic user, addiction, or psychological dependence, is mediated through specific neurotransmitter pathways. Although there are no well-defined syndromes constituting cocaine withdrawal, patients may have strong cravings for the drug or a general feeling of dysphoria that is not physiologically life-threatening.

DIFFERENTIAL CONSIDERATIONS

A differential diagnosis of acute cocaine intoxication considers the various causes of agitated delirium (Box 152-2). A thorough

CNS, central nervous system.
assessment of mental status, vital signs, and physical examination can help direct and narrow the differential diagnosis. Conditions that may be indistinguishable from cocaine intoxication include sedative-hypnotic withdrawal, intoxication from amphetamines and amphetamine derivatives, and heatstroke. Phencyclidine intoxication may be distinguished by the presence of multidirectional nystagmus, but the treatment is similar. Patients with anticholinergic poisoning typically have urinary retention, dry skin, and minimally reactive pupils as distinguishing factors. Infection should be considered in all hyperthermic patients.

**MANAGEMENT**

A severely poisoned patient is combative and unable to cooperate in assessment of vital signs. These first few moments are crucial (Box 152-3). Because the patient’s history is not always clear, the initial goal is to recognize and treat the rapidly life-threatening agitated delirium.

After initial airway assessment, patients may transiently require physical restraints to obtain complete vital signs and to secure IV access. If a chest restraint is used, a mesh vest is preferred to a jacket to help limit hyperthermia. The patient can receive empirical therapy with IV dextrose and thiamine or assessment with a bedside blood glucose monitor. Immediate pharmacologic sedation with IV benzodiazepines may be necessary, which, in adequate doses, restores inhibitory tone to the CNS and decreases excessive sympathetic outflow to peripheral tissues. Sedation also facilitates measurement of vital signs, particularly core temperature, continuous ECG monitoring, and completion of the physical examination.

**Pharmacologic Sedation**

In adults, IV diazepam can be administered in increments of 10 mg every 5 minutes until sedation is achieved. Diazepam has a rapid onset of action, is easily titratable, and has active metabolites for a sustained effect. Persistently increased motor tone reflects an inadequate diazepam dose, even if the patient appears sleepy. In wildly agitated patients in whom 20 to 30 mg of diazepam has no notable effect, the increments may be increased carefully by 20 mg each subsequent dose with close monitoring. Benzodiazepines also treat the choreothetoid movements of crack-dancing. Most cocaine intoxicated patients have salt and water depletion and require vigorous IV crystalloid replacement. If the cause of delirium is unclear, careful attention to the patient’s respiratory status avoids the respiratory depression caused by excessive benzodiazepine administration in the presence of other sedative-hypnotic agents, such as ethanol.

Phenothiazines, droperidol, and haloperidol are ideally avoided if possible in patients thought to be acutely intoxicated with a sympathomimetic. Although they have a rapid onset with intramuscular injection and CNS sedation is achieved, the anticholinergic effects of these agents can theoretically limit cooling by impeding diaphoresis and may also have associated dysrhythmic effects that may be additive to cocaine.

**Hyperthermia**

Cocaine-induced hyperthermia must be treated with rapid cooling (Box 152-4). Patients who sustain elevated core temperatures greater than 106°F (41°C) for more than 20 minutes are likely to stabilize transiently, then develop fatal multisystem organ failure, often heralded by disseminated intravascular coagulation. Patients should have continuous monitoring of core temperature with a rectal probe. Heat generated by agitation and increased muscle tone can be terminated by aggressive use of benzodiazepines, with neuromuscular paralysis and intubation as required. It is crucial to reduce core temperature to 102°F (38.8°C) within 20 minutes. Cooling blankets are insufficient. Ice water, wet sheets with large fans, and packing the entire body in ice with continuous monitoring of core temperature can be used. These patients often require aggressive fluid resuscitation.

**Hypertensive Emergencies**

The goal in hypertensive emergencies is to promptly reverse the vasoconstriction of norepinephrine at peripheral alpha-adrenergic receptors. Benzodiazepines restore the CNS inhibitory tone on the peripheral nervous system. With evidence of end-organ damage, IV nitroglycerin or nitroprusside can be used. Phenolamine, a direct alpha-adrenergic antagonist, is the antihypertensive of choice. It can be titrated slowly using repeat IV doses of 1 to 5 mg with blood pressure monitoring. In contrast to chronic hypertension, individuals with acute cocaine hypertension often have a normal blood pressure in the absence of the drug, and unless the patient’s history suggests otherwise, a normal systolic and diastolic blood pressure should be the endpoint of therapy. Beta-adrenergic antagonists may cause paradoxical hypertension with cocaine. Patients undergoing cardiac catheterization show decreased coronary artery diameter in the presence of cocaine and beta-adrenergic antagonists. Beta-adrenergic antagonists use in cocaine toxicity or cocaine-related chest pain syndromes should be avoided while its role is investigated. The treatment of cocaine-induced subarachnoid hemorrhage, myocardial infarction (MI), or aortic dissection differs from treatment

**BOX 152-3** INITIAL EVALUATION OF PATIENTS WITH SYMPATHETIC STIMULATION

- Rapid assessment of vital signs, especially core temperature
- Rule out hypoxia, hypoglycemia
- Pharmacologic sedation with benzodiazepines
- Electrocardiogram
- Urinalysis
- Serum creatinine phosphokinase

**BOX 152-4** MANAGEMENT OF STIMULANT-INDUCED HYPERThERMIA

- Early identification of elevated core temperature
- Large-bore intravenous access with rapid infusion of crystalloid
- Sedation and muscle relaxation with benzodiazepines
- Rapid cooling within 20 min*
- Foley catheterization to monitor output
- Laboratory analysis for organ function
  - Serum chemistries/creatinine/CK
  - Liver function
  - PT/PTT/fibrin split products
  - Bacterial cultures†
- Urinalysis for myoglobinuria
- Paralysis and intubation if necessary

*Ideally with ice water immersion.
†Consider lumbar puncture or antibiotic therapy, especially in injection drug users.
CK, creatine kinase; PT, prothrombin time; PTT, partial thromboplastin time.
for other causes of the same conditions. The combined use of phentolamine and beta-adrenergic antagonists may result in profound hypotension and is inadequately investigated. Likewise, data on the use of labetalol are disappointing. The 2008 American Heart Association Guidelines consider beta-adrenergic antagonists potentially harmful.43

**Dysrhythmias**

Dysrhythmias from cocaine may be either atrial or ventricular. Atrial fibrillation and supraventricular tachycardias are likely due to sympathetic stimulation and often respond to benzodiazepines. Beta-adrenergic antagonists should be avoided.

When the cause of a wide-complex tachycardia from cocaine is unknown, an empirical sodium bicarbonate, 1 to 2 mEq/kg IV bolus, with closely recorded cardiac monitoring treats sodium channel blockade and potential cardiotoxicity from hyperkalemia.64,65 Lidocaine, a class IB antisydhrhythmic agent, may increase seizure risk and mortality and is therefore reserved for patients with ventricular dysrhythmias for whom bicarbonate therapy has failed and who have already received benzodiazepines. Lidocaine may be most useful for ventricular dysrhythmias with cocaine-associated MI. Amiodarone is not well studied, but may be beneficial for ventricular dysrhythmias.45 Close monitoring is required for patients with a Brugada-type conduction pattern.24,25

**Cocaine-Related Chest Pain**

The causes of cocaine-related chest pain are diverse (Box 152-5). A chest radiograph may identify aspirated foreign bodies or pneumothorax or pneumomediastinum from inhalational barotrauma. Fever and shortness of breath should prompt consideration of pneumonia, pulmonary infarction,46,47 or endocarditis due to vasoactive metabolites.51 The patient may present hours to days after use, with body packers containing approximately 10 g of cocaine, and packers may swallow as many as 150 packets.58,59 On arrival at the patient’s destination, a cathartic is taken to stimulate gastrointestinal passage of the contraband for subsequent delivery and distribution. Body packers are likely to know the exact number of packets they ingested.

Before crossing international borders, “body packers” ingest cocaine that has been wrapped tightly into condoms or other latex products and sometimes coated in wax. Each packet can contain approximately 10 g of cocaine, and packers may swallow as many as 150 packets.36,53 On arrival at the patient’s destination, a cathartic is taken to stimulate gastrointestinal passage of the contraband for subsequent delivery and distribution. Body packers are likely to know the exact number of packets they ingested.

A body packer may present without symptoms to the emergency department. The body packer should be placed immediately on continuous cardiac monitoring, with large-bore IV

**Cocaine Body Packers**

Before crossing international borders, “body packers” ingest cocaine that has been wrapped tightly into condoms or other latex products and sometimes coated in wax. Each packet can contain approximately 10 g of cocaine, and packers may swallow as many as 150 packets.36,53 On arrival at the patient’s destination, a cathartic is taken to stimulate gastrointestinal passage of the contraband for subsequent delivery and distribution. Body packers are likely to know the exact number of packets they ingested.

A body packer may present without symptoms to the emergency department. The body packer should be placed immediately on continuous cardiac monitoring, with large-bore IV
access. Diagnosis is made by history. An abdominal radiograph may confirm foreign bodies but cannot be used to count packets because plain radiographs have limited sensitivity in detecting an isolated or small number of packets. When uncertainty persists, a contrast study is warranted. Body packing also is used for transporting heroin and other illicit substances. Although heroin body packing rarely requires surgical intervention, an asymptomatic patient may refuse to identify the packet’s contents. A urine toxicology screen may be useful because some fine quantities of drug may be directly ingested while swallowing the contraband. Body packers with a positive urine screen for cocaine metabolites should receive vigorous decontamination.

Rupture of a single cocaine packet can result in death because each packet contains almost 10 times the lethal dose. These patients may die suddenly. All cocaine body packers should be admitted to a monitored setting and given nothing to eat or drink. Patients with a leaking or poorly secured packet who become symptomatic meet the single absolute criterion for surgical removal of packets and are likely to die without prompt intervention. When evidence of cocaine toxicity is manifest, rapid transportation to the operating room may be the only way to save these patients. Benzodiazepines, neuromuscular blockade, or sodium bicarbonate administration may be required en route.

It is reasonable to administer activated charcoal (1 g/kg body weight) to an asymptomatic body packer whose airway is intact. Whole-bowel irrigation with polyethylene glycol solution facilitates gastrointestinal passage of the packets and cleanses the bowel in the event of emergent transport to the operating room. Subsequent contrast studies may be required to evaluate for remaining packets. Computed tomography and contrast abdominal radiographs may fail to detect isolated packets that contain potentially fatal quantities of cocaine. Patients suggesting that they swallowed a larger number of packets than passed or who refuse to reveal the number ingested warrant continued bowel irrigation, observation, and repeat studies. Endoscopic retrieval is discouraged because of concern over packet rupture during the procedure.

All packets passed in the stool, via endoscopic procedures, or in the operating room should be counted carefully and promptly given to law enforcement officials. When law enforcement is not yet involved, hospital legal counsel or risk management and the hospital ethics committee may be helpful in determining the disposition of the packets and ultimately of the patient when he or she is medically cleared.

Body Stuffers
A “body stuffer” is an individual who attempts to conceal evidence of cocaine possession by swallowing the drug while pursued by law enforcement officials. These are usually unplanned events with generally small quantities of drug intended for personal use. The drugs are often swallowed in poorly sealed vials or glassine packets that may not be evident on radiographs. Generally, patients ingest nonlethal doses and are asymptomatic. Activated charcoal (50 g) can absorb any potentially released drug. Monitoring and whole-bowel irrigation should be performed if the quantity ingested is of concern or if signs of intoxication persist. Stuffers rarely have fatal events, but these patients usually present with or develop symptoms in the first few hours.

DISPOSITION
Acutely intoxicated patients who need only observation or who respond quickly to sedation and do not develop complications can be discharged after the acute intoxication resolves.

These patients may be extremely sleepy from catecholamine depletion, and it is best to discharge them with a responsible adult. Patients may be open to drug counseling and referral while in the emergency department. Patients who develop complications should be admitted to the intensive care unit for further treatment.

Patients with chest pain (Box 152-6) who are acutely intoxicated and who show dynamic changes on the ECG, dysrhythmias, or congestive heart failure or patients requiring vasodilators or reperfusion should be admitted. These patients require further evaluation of the extent of preexisting reversible ischemia and intervention to encourage cessation of drug use.

The disposition of patients with chest pain who are not acutely intoxicated is less clear. Admission is warranted for patients with complications or ECG changes and patients requiring pharmacologic intervention. Other patients may be admitted for short-term observation to an emergency department observation unit or discharged, depending on the level of concern about underlying coronary artery disease.

Young patients who present after resolution of chest pain with normal, unchanged ECGs, no dysrhythmias, and few or no risks of coronary artery disease are likely to have a good outcome. Complications such as congestive heart failure and ventricular dysrhythmias typically present within the first 4 hours. After a 12-hour monitored observation period, patients with a benign clinical course and negative serum enzyme markers can be discharged.

Body packers need to be observed until all packets have passed. Ideally, these patients have had three packet-free stools, a reliable packet count consistent with the ingestion, and a negative contrast radiographic study. Body stuffers who receive activated charcoal, have normal ECGs, and remain asymptomatic with normal vital signs after 4 to 6 hours of observation may be discharged.

OTHER STIMULANTS
Amphetamines
Amphetamines enhance release of catecholamines from presynaptic nerve terminals by altering the pH of presynaptic vesicles. Amphetamines are usually taken as pills, but occasionally are crushed and injected. The subsequent CNS stimulation results in nearly identical sympathomimetic effects to those from cocaine, but not with the same frequency or intensity (see Box 152-1). Patients are at risk for hyperthermia, hypertensive emergencies, dysrhythmias, myocardial ischemia, and hyperkalemia associated with rhabdomyolysis. In contrast to cocaine, amphetamines do not block sodium channels and only minimally affect presynaptic reuptake of catecholamines. Although urine drug screens can identify amphetamines, they are of little utility in treating an intoxication.
cated patient. The management follows the same guidelines as for cocaine (see Box 152-3), although the duration of toxicity tends to be longer for amphetamines.

**Methylenedioxymethamphetamine**

Methylenedioxymethamphetamine (MDMA—“Ecstasy,” XTC, Adam) is a chemically modified amphetamine originally taken orally at all-night dance parties, or “raves.” Patients describe the euphoria allowing “closeness to others,” so it is sometimes called the “love drug.” The molecular structure of MDMA confers some serotonergic properties that may account for the “shimmering” visual effects reported.

Along with the usual complications of amphetamines, MDMA can precipitate a life-threatening hyponatremia. MDMA or its metabolite may alter release of endogenous stores of vasopressin. Although the exact mechanism is not understood, patients with MDMA-induced hyponatremia have concentrated urine samples with a relatively high urine sodium level, similar to syndrome of inappropriate antidiuretic hormone. Unless seizures or other neurologic events are present, patients can be treated supportively with fluid restriction. Urine can be tested for specific gravity, and a sample should be sent to the laboratory for electrolyte analysis and osmolality. Normal saline or other crystalloids may worsen the hyponatremia because these patients are likely to retain more free water than sodium. Their fluid intake should be restricted unless severe hypovolemia exists, and they should be treated with hypertonic saline for neurologic impairment. A newer treatment for hyponatremia includes vasopressin-receptor antagonists but has not been described for these patients. In contrast to other amphetamines, chronic MDMA use causes potentially irreversible neurologic damage to serotonergic neurons. Other MDMA variants, such as 3,4-methylenedioxymethamphetamine (Eve), may cause similar complications (see Chapter 154).

**Methamphetamine**

Methamphetamine, known as “crank” and “crystal meth,” is a fat-soluble, smokable, designer amphetamine. Complications from methamphetamine use are similar to those from other sympathomimetics. The duration of action can be significantly longer, however, with some paranoid delusions persisting for 15 hours. The production of methamphetamines requires a variety of metal salts, and lead toxicity from inappropriately produced drug is reported. Injuries during illicit methamphetamine production or police raids include exposure to anhydrous ammonia, hydrochloric acid, sodium hydroxide, ether, and ephedrine, as well as burns and explosions.

**Ephedrine and Ephedra**

Ephedrine is another illicitly used amphetamine-like agent associated with complications of excessive sympathomimetic stimulation. Ephedra, a plant-derived product, also known as a Chinese herbal product, ma-huang, has been associated with strokes and deaths in adolescent users. The U.S. Food and Drug Administration has banned all ephedra-containing dietary supplements.

**Khat and Methcathinone**

Khat is a stimulant agent naturally occurring in the leaves of the plant *Catha edulis*. These leaves are chewed to extract the active compounds, cathinone and methcathinone, which are stimulants with sympathomimetic effects. Management and disposition follow the same guidelines as that of cocaine. Smoking khat does not typically result in clinical effects because the agent degrades with pyrolysis. Illicitly manufactured methcathinone is known as “cat.” Some methcathinone users experienced an extrapyramidal syndrome associated with elevated manganese levels likely resulting from an inadvertent contaminant during production or inadequate purification. The role of chelation therapy for elevated manganese levels is uncertain.

**KEY CONCEPTS**

- Rapid sedation with an IV benzodiazepine is the key for most symptoms from cocaine and other stimulants.
- Hyperthermia is a high-risk sign, and body temperature must be reduced rapidly.
- Beta-adrenergic blockade may cause paradoxical hypertension and increase coronary vasoconstriction and is generally contraindicated.
- Wide-complex rhythms secondary to cocaine may respond to IV bicarbonate therapy.
- Cocaine body packers who become symptomatic need immediate surgery.
- Amphetamine symptoms and effects last longer than those produced by cocaine.

METHANOL

Perspective
Methanol is a colorless, volatile, slightly sweet-tasting alcohol. It is a product of natural fermentation and originally was manufactured from the distillation of wood. Methanol currently is produced almost exclusively by synthetic pathways. Certain products found in the home, including antifreeze; windshield washer fluid; carburetor fluid; duplicator fluid; hobby engine fuel; gasohol; dry gas; Sterno; glass cleaners; and thinners for shellacs, lacquers, adhesives, and inks may contain high concentrations of methanol. Methanol is a precursor in the manufacture of plastics, films, and dyes. Methanol is also found in formalin and embalming fluid. Illicit alcohol production remains a global source of methanol poisoning from products such as chang’aa (Kenya), raki (Turkey), and tuica (Romania).

Although epidemic poisonings from methanol are reported occasionally, most exposures are sporadic. In 2006, of the 2086 cases of methanol poisoning reported to American poison centers, 73% were unintentional, 8% had moderate to major complications, and 8 resulted in fatalities. Treatment delay is associated with increased morbidity, making early recognition of clinical and laboratory clues crucial.

Principles of Disease
Pharmacology and Metabolism
Methanol is absorbed rapidly from the gastrointestinal tract, and blood levels peak 30 to 60 minutes after ingestion. Transdermal and respiratory tract absorption also has resulted in toxicity, especially in infants. Certain occupations, including painting, glazing, varnishing, lithography, and printing, are at high risk for inhalational exposure to methanol. Inhalational abuse of methanol is a recent trend that can result in toxic serum levels. At low serum concentrations, the elimination of methanol follows first-order kinetics; at concentrations after overdose, zero-order kinetics predominate. A prolonged half-life of 24 to 30 hours results, which may be extended even further by the concurrent ingestion of ethanol. First-order elimination prevails at high levels (>300 mg/dL), possibly as a result of enhanced pulmonary elimination. Small amounts of ingested methanol may be exceptionally toxic. In adults, the smallest lethal dose reported is 15 mL of 40% methanol; 4 mL of pure methanol has led to blindness. With appropriate, timely treatment, however, survival without loss of eyesight has been reported despite extremely high levels. From a pediatric perspective, the ingestion of only 1.5 mL of 100% methanol in a toddler (0.15 mL/kg) is sufficient to produce a toxic blood level of 20 mg/dL. Any suggested pediatric methanol ingestion warrants aggressive evaluation and treatment.

Methanol itself has little toxicity, producing less central nervous system (CNS) depression and inebriation than ethanol. Metabolites of the parent alcohol are extremely toxic, however. Although small amounts of methanol are eliminated via renal and pulmonary routes, 90% is metabolized hepatically. Methanol is oxidized by alcohol dehydrogenase (ADH) to formaldehyde, which is rapidly converted by aldehyde dehydrogenase to formic acid (Fig. 153-1). Formic acid is the primary toxicant and accounts for much of the anion gap metabolic acidosis and ocular toxicity peculiar to methanol ingestion. Through a folate-dependent pathway, formic acid is degraded to carbon dioxide and water.

Pathophysiology
Optic neuropathy and putaminal necrosis are the two main complications of severe methanol poisoning. Long-term morbidity takes the form of visual impairment, including blindness, and parkinsonian motor dysfunction, characterized by hypokinesia and rigidity. Formic acid has a high affinity for iron and, as such, inhibits mitochondrial cytochrome oxidase, halting cellular respiration. Methanol metabolism in the cytosol and mitochondria may account for a second mechanism of adenosine triphosphate depletion. Lactate accumulation resulting from hypotension or seizures further compounds the metabolic acidosis predominantly caused by formate. Other mechanisms of toxicity involve increased lipid peroxidation, free radical formation, and impaired protective antioxidant reactions. Severe dysfunction of subcellular metabolism from methanol also has been linked to significant disturbance in proteolytic-antiproteolytic balance.

The primary sites of ocular injury are the retrolaminar optic nerve and retina. Selective myelin damage to the retrolaminar optic nerve has been seen at autopsy in patients dying as a result of methanol toxicity. Müller cells, the principal glial cells of retinal neurons and photoreceptors, have been proposed as the initial target in methanol-induced visual toxicity. It seems that they alone harbor the enzymes necessary to metabolize methanol to formate. Histopathologic correlates suggest that retinal cells develop intra-axonal swelling, calcium influx, mitochondrial destruction, and microtubular disruption. Ultimately, interference with transport of essential proteins from the retinal neuron cell body to the nerve fiber axoplasm.
results. Oligodendrocyte involvement results in myelin degeneration and leads to visual decrements. Acidosis may accelerate this process, by enhancing nonionic diffusion of formic acid into neurons and further increasing lactate production. This self-perpetuating cycle of acidosis, termed *circulus hypoxicus*, underscores the need for aggressive correction of pH to accomplish ion trapping of formate outside the CNS.

Methanol adversely affects other areas of the CNS, specifically the basal ganglia. Bilateral, symmetrical putaminal hypodensities, hemorrhages, or cystic lesions are characteristic, occurring in 13.5% of patients. Necrosis is described in the subcortical white matter, spinal cord anterior horn cells, and cerebellum. Acute signs and symptoms may be lacking or may take several days to develop, despite the presence of these radiographic findings. The cellular mechanisms of injury may be similar to the mechanisms of the ophthalmologic injury, but the reason for localization of neurologic damage to the basal ganglia is unknown. Although some quantitative neuropathologic studies have shown high concentrations of formic acid within the putamen, others show that formate levels are not disproportionately elevated in these areas compared with levels in the blood or other tissues. Massive edema adjacent to the putamen shown by magnetic resonance imaging (MRI) suggests a possible localized disruption of the blood-brain barrier. Other proposed mechanisms for the vulnerability of this region include the unique pattern of arterial blood supply and venous drainage and greater metabolic activity.

**Clinical Features**

With individual cases of methanol poisoning, the history may be unobtainable or unreliable. The diagnosis should be considered in patients with altered mental status, visual complaints, or metabolic acidosis or in patients with occupations that put them at high risk for exposure. Because methanol is a poor substrate for ADH, a latency period exists between the time of ingestion and onset of visual or metabolic disturbance. The typical 12- to 24-hour latency may be shorter when large amounts are consumed or longer when ethanol is co-ingested (range 40 min to 72 hr). In patients who present early, formic acid accumulation may be ongoing, with risk for significant toxicity despite being asymptomatic. When symptoms manifest, they are primarily neurologic, gastrointestinal, or ocular in nature.

Although methanol is less inebriating than ethanol, early symptoms of methanol poisoning are depressed mental status, confusion, and ataxia. Nonspecific complaints of weakness, dizziness, anorexia, headache, and nausea develop. In severe cases, coma and seizures may be seen. Although vomiting and abdominal pain commonly result from mucosal irritation, the absence of gastrointestinal complaints does not rule out a serious ingestion. Abdominal tenderness, however, may be so severe that it suggests an acute surgical abdomen. This may result from pancreatitis, and elevation of serum amylase is relatively common. Other authors have noted increased salivary amylase isoenzyme without pancreatic inflammation.

Visual disturbances are seen in 50% of patients, and their development may precede or parallel that of other clinical symptoms. Patients may complain of cloudy, blurred, indistinct, or misty vision or may note yellow spots or, rarely, photophobia. The most common acute field defect is a dense central scotoma. Some patients compare their visual symptoms with “stepping out into a snowstorm,” a complaint unique to methanol ingestion. Patients can have a complete lack of light perception and total loss of vision. On examination, optic disk hyperemia is seen at 18 to 48 hours after ingestion. Peripapillary retinal edema follows, is most striking in the nerve fiber layer along the vascular arcades, and only rarely involves the macula. Sluggishly reactive or fixed and dilated pupils indicate a poor prognosis. Pallor and cupping, indicative of optic atrophy, are late findings suggesting a poor prognosis for visual recovery. Occasionally, the fundus may appear normal, even in patients with visual symptoms.

Compensatory tachypnea heralds the onset of metabolic acidosis, which often may be severe, with reported serum bicarbonate concentrations of less than 5 mEq/L and an arterial pH less than 7.0. Early tachycardia has been noted, but in general, cardiovascular abnormalities are rare. Hypotension and bradycardia, when present, are preterminal findings. Historically, death was described in association with a peculiar, abrupt cessation of respiration, rather than with cardiovascular collapse. Rarely, multiple organ failure develops.

Prognosis after methanol ingestion seems to correlate with the degree of acidosis, time to presentation, and initiation of treatment within 8 hours of exposure. Poor prognosis is associated with coma, seizures, or arterial pH less than 7.0. A recent large outbreak was associated with a fatality rate of 44%. Patients surviving the acute phase of toxicity may be left with permanent blindness or neurologic deficits, such as parkinsonism, toxic encephalopathy, polyneuropathy, cognitive dysfunction, transverse myelitis, primitive reflexes, or seizures.

**Diagnostic Strategies**

A severe anion gap metabolic acidosis is the hallmark of methanol poisoning. In some cases, this sign may be the only diagnostic clue. Because the onset of acidosis may be delayed 12 to 24 hours, the presence of a normal anion gap does not rule out methanol exposure. Absence of high anion gap acidosis has been described in cases with concomitant ethanol, lithium, or bromide ingestion. In methanol toxicity, this anion gap is due primarily to the presence of formic acid, with a variable contribution from lactic acid. Another classic laboratory finding in methanol toxicity is an elevated osmol gap. The osmol gap is defined as follows:

\[
\text{Osmol gap} = \text{measured serum osmolality} - \text{calculated serum osmolality}
\]

Serum osmolality depends on the presence of low-molecular-weight solutes, primarily sodium, chloride, glucose, and blood urea nitrogen (BUN). One formula for calculating osmolality attributable to these solutes is as follows:

\[
\text{Calculated serum osmolality} (mOsm/kg) = 2(\text{Na}^+) + [\text{BUN}/2.8] + [\text{glucose}/18] + [\text{ethanol} (mg/dL)/4.6]
\]
The “normal” osmol gap is often cited to be less than 10 mOsm/kg when the preceding equation is used. This is an arbitrary number, and there is considerable variability in baseline osmolal gaps in patients, particularly children. An osmol gap significantly greater than 10 mOsm/kg may be a useful aid in the diagnosis of toxic alcohol ingestion. Caution should be taken, however, in ruling out toxic alcohol ingestion with a “normal” osmol gap for several reasons. First, calculated serum osmolality results may vary among laboratories and must be done by the freezing point depression method. Also, delayed presentation after toxic alcohol ingestion may be associated with prior metabolism of most of the parent alcohol. Because only the parent compound is osmotically active, and because the charged metabolites are electrically balanced by sodium, there may be little or no osmol gap elevation in this setting. Finally, a toxic level of either methanol or ethylene glycol may be present with a gap of only 10 mOsm/kg. If there is clinical suggestion of toxic alcohol ingestion, direct measurement of the serum toxic alcohol level is necessary, and if not readily available, empirical treatment is warranted. In addition to methanol, ethylene glycol, and isopropanol, other low-molecular-weight solutes, such as ethanol, acetone, propylene glycol, mannitol, glycerol, and ethyl ether, may cause elevated osmol gaps. Rhabdomyolysis, pancreatitis, and metabolic derangements, such as hypomagnesemia, hypokalemia, and hypophosphatemia, are also described with methanol poisoning.

Computed tomography may be indicated in an intoxicated patient with altered mental status. The characteristic finding of bilateral putaminal lesions suggests methanol poisoning, but this finding also may be seen with Leigh’s syndrome, Wilson’s disease, hypoxic-ischemic insult, encephalitis, and certain metabolic disorders. Ischemic necrosis, cerebral edema, or brain hemorrhages also may be noted. Follow-up scans may have prognostic value because parkinsonian features are unlikely to develop in patients whose putaminal lesions resolve within a short time frame. MRI may also detect putaminal aberrations or optic neuropathy from methanol intoxication.

Differential Considerations

Methanol and ethylene glycol cause inebriation and are ingested as ethanol substitutes. The differential diagnosis of a patient with altered mental status includes hypoglycemia, head trauma, postictal state, carbon dioxide narcosis, hypoxia, infection, hepatic encephalopathy, other metabolic disorders, thiamine deficiency, endocrinopathy, drug abuse, and other poisoning. Patients who present with severe abdominal pain and altered mental status could slant the differential diagnosis toward a long list of intra-abdominal entities. When an anion gap acidosis is identified, however, the differential diagnosis must be tapered toward entities that cause this, and a primary decision must be made regarding whether the acidosis is a result of an ingested toxin or some other cause (e.g., mesenteric ischemia, diabetic ketoacidosis). Usually, the presence of an ingestion is admitted by the patient or strongly considered by the providers, but this is not always the case, especially when the patient has depressed mental status of unknown cause. Causes of an elevated anion gap in patients without evidence of renal failure, hypotension, hypoxemia, diabetes, seizures, or alcoholism include methanol, ethylene glycol, paraldehyde, isoniazid, iron, salicylates, tolune, or lactic acidosis from myriad toxicants, including metformin, carbon monoxide, cyanide, and cocaine. Ethylene glycol and methanol may cause a “double gap” (i.e., an osmol gap in addition to the anion gap). Other substances that contribute to an elevated osmol gap include isopropyl alcohol, ethanol, propylene glycol, mannitol, glycerol, and ethyl ether. Other situations in which double-gap acidosis may be encountered include diabetic ketoacidosis; alcoholic ketoacidosis; acetoniitrile, methanol, ethylene glycol, and propylene glycol toxicity; multiple organ failure; chronic renal failure; and critical illness. Hyperlipidemia and hyperproteinemia, by decreasing the measured sodium concentration, can increase the osmolal gap. Characteristically, isopropanol does not cause an increased anion gap.

Certain unusual characteristics of methanol and ethylene glycol intoxication lead to the specific diagnosis. The presence of ocular complaints unique to methanol poisoning is a valuable clue. Ethylene glycol ingestion often is associated with calcium oxalate crystalluria, which is not seen in methanol ingestion. Ultimately, the definitive diagnosis depends on the identification of the parent alcohol in the blood by laboratory tests that may not be routinely available. It is often necessary to start treatment based on clinical suggestion alone. Because the initial treatment for methanol and ethylene glycol is almost identical, identification of the specific toxic alcohol is not crucial to the initiation of therapy.

Management and Disposition

See the discussion on management in the following section on ethylene glycol.

**ETHYLENE GLYCOL**

**Perspective**

Ethylene glycol is a viscous, colorless, odorless, slightly sweet-tasting liquid. Because it lowers the freezing point of water, its primary utility is as a commercial antifreeze or coolant. Other sources include airplane deicing solutions, hydraulic brake fluids, and industrial solvents/precursors; it also is a component of certain paints, lacquers, and cosmetics. Most ethylene glycol poisonings occur with the ingestion of antifreeze. Unusual poisoning scenarios are described, including an epidemic after the contamination of water supplies and the intentional poisoning of an infant, presenting as an inherited metabolic disorder. In 2006, the American Association of Poison Control Centers reported 6135 exposures to ethylene glycol. Of those exposures, 74% were unintentional, and 11% resulted in moderate or severe effects; there were 34 fatalities. If treated early and aggressively, ethylene glycol poisoning is unlikely to result in death. Conversely, failure to recognize and treat ethylene glycol ingestion may result in multiorgan failure and death within 24 to 36 hours.

**Principles of Disease**

**Pharmacology and Metabolism**

Absorption of ethylene glycol is rapid after ingestion. It distributes evenly to tissues with a volume similar to that of body water. Peak blood levels are reached within 1 to 4 hours after ingestion. In contrast to methanol and isopropanol, ethylene glycol is nonvolatile at room temperature so absorption via inhalation is unlikely. Reported half-lives range from 3 to 8.6 hours. When metabolism is blocked by fomepizole or ethanol, the half-life increases to 11 to 15 hours or 17 hours, respectively. The toxic and lethal doses of 100% ethylene glycol have been reported as 0.2 mL/kg and 1.4 mL/kg. At the other extreme, with therapeutic advances, patients who have ingested 3000 mL have survived. Twenty-seven percent of ethylene glycol is excreted unchanged by the kidneys. The remainder is hepatically oxidized via ADH and other oxidative

Chapter 153 / Toxic Alcohols
Pathophysiology

Unmetabolized ethylene glycol has limited toxicity, yet all metabolites are toxic. In humans, 2.5% of a dose of ethylene glycol ultimately is converted to oxalic acid, most of which is excreted in the urine. A fraction of oxalic acid combines with calcium to form calcium oxalate crystals, which precipitate in renal tubules, brain, and other tissues. Although calcium oxalate crystals previously were thought to be the most significant cause of renal toxicity, much of ethylene glycol's nephrotoxic effect now is known to stem from the direct cytotoxic action of the organic acid metabolites themselves. When administered to rats, the ethylene glycol metabolites glycolate, glyoxylic acid, and glycoaldehyde cause significant renal toxicity in the absence of calcium oxalate crystal deposition. Persistent deposition of these crystals has been observed in serial renal biopsy specimens despite recovery. An in vitro study on human proximal tubular cells showed that toxicity occurred primarily from the direct effect of oxalic acid, despite exposure to much higher levels of glycolate. Other authors suggest that glycolate levels correlate better with disruption of CNS metabolism, the development of renal failure, and mortality. An intermediary of glycolic acid metabolism, glyoxylic acid, theoretically can be shunted toward pyridoxine-dependent or thiamine-dependent pathways, which generate the nontoxic intermediary of glycolic acid metabolism, glyoxylic acid, theopyridoxine-dependent or thiamine-dependent pathways, which generate the nontoxic intermediary of glycolic acid metabolism, glyoxylic acid, theoxylate and glycolate.28 Other authors suggest that glycolate levels correlate better with disruption of CNS metabolism, the development of renal failure, and mortality.29

Histologically, proximal renal tubular dilation with hydropic degeneration, intratubular crystal deposition, and edema of the interstitium are seen. Relative sparing of the glomeruli is typical, although glomerular interloop space crystal deposition may occur. Glomerular function is preserved, but tubular dysfunction manifesting as protein leak is noted.27 Neuropathologic changes induced by ethylene glycol include diffuse calcium oxalate deposition with petechial hemorrhages in the retina, brain, vessel walls, and perivascular spaces, with evidence of cerebral edema and chemical meningoencephalitis. Similar changes also have been noted in the liver, spleen, pancreas, pleura, lungs, pericardium, and blood vessel walls throughout the body. Myonecrosis occurs in skeletal and myocardial muscle, and rhabdomyolysis and myocardial dilation occur.26 Fatty liver with focal necrosis has been noted.

The metabolism of ethylene glycol results in a profound anion gap metabolic acidosis caused mainly by glycolic acid.29 Lactate elevation, triggered by the altered redox potential within cells and inhibition of the citric acid cycle by products of glyoxylate metabolism, is a minor contributing factor to the severe acidosis.29

Clinical Features

The clinical syndrome with ethylene glycol ingestion is divided into four stages: acute neurologic stage, cardiopulmonary stage, renal stage, and delayed neurologic sequelae stage. The severity of illness seen in each stage varies, as does progression through stages, which may be telescoped. Patients may die in any stage of ethylene glycol poisoning. Poor prognostic factors include hyperkalemia, severe acidosis, seizures, and coma. Metabolic acidosis and symptoms typically occur within 4 to 8 hours, but may be delayed for 12 hours or longer if ethanol has been co-ingested.

Stage I, the acute neurologic stage, occurs 30 minutes to 12 hours after ingestion. The parent alcohol causes approximately the same degree of inebriation as ethanol with CNS depression, slurred speech, nystagmus, ataxia, and vomiting. With large ingestions, more dramatic neurologic findings, such as hallucinations, convulsions, or coma, may be present during the early phase of intoxication. Ocular findings, similar to methanol intoxication, including decreased pupillary reflexes, decreased visual acuity, optic disk blurring, papilledema, and loss of color discrimination, are reported but methanol exposure was not ruled out in most of these case reports.

Stage II, the cardiopulmonary stage, occurs 12 to 24 hours after ingestion. Often, the patient exhibits mild hypertension and tachycardia. Tachypnea may reflect the underlying profound metabolic acidosis or may herald the onset of cardiogenic or noncardiogenic pulmonary edema.8 The mechanism of acute respiratory distress syndrome (ARDS) is unclear but may be related to the toxicity of glycolic and glyoxylic acids and to the deposition of calcium oxalate crystals within the lungs. Pulmonary infiltrates are described during this phase. Circulatory collapse may occur as a result of myocardial depression. Hypocalcemia, rarely associated with tetany or cardiac dysrhythmia, occurs in 30% of patients as a result of systemic chelation of calcium by oxalate.26 Myositis with muscle tenderness and creatine kinase (CK) elevation results from skeletal muscle inflammation and necrosis.

Stage III, the renal stage, occurs 24 to 72 hours after ingestion. In one epidemic of 36 patients, renal damage was noted in 67%.26 Awake patients may complain of flank pain or have costophrenic angle tenderness. Calcium oxalate monohydrate or dihydrate crystalluria is seen in only 50% of cases.24 Hematuria and proteinuria are common, however. As with other causes of acute tubular necrosis, oliguria is not always present but may develop 12 hours after ingestion and may progress to frank anuria. The outcome has not been well studied in patients who develop renal failure. Prolonged hemodialysis may be necessary, although recovery of renal function has been reported. Delayed onset of ARDS has been reported to occur during this stage, but more typically is seen in stage II. The degree of acidosis, delay in presentation, and glycolate levels correlate better with the development of renal failure than do ethylene glycol levels.26,31

Stage IV, the delayed neurologic sequelae stage, occurs 6 to 12 days after ingestion and typically manifests as cranial neuropathy.32 All cases have been associated with renal failure. Facial diplegia, occasionally with deafness, is encountered most frequently. Other reported findings include dysarthria, dysphagia, tongue deviation, visual deterioration, and internal opthalmoplegia. Delayed and persistent cognitive and motor deficits, such as ataxia, chorea, coma, and late personality...
changes, also are reported. Total paralysis from severe axonal peripheral polyneuropathic degeneration with oxalate deposition is reported, \textsuperscript{23} as is polyradiculopathy from nerve root (not distal) pathology. Although some improvement in neurologic status has been noted at follow-up, most patients are left with residual neurologic deficits. Some authors have coined this delayed syndrome \textit{facial auditory nerve oxalosis}, based on heavy calcium oxalate crystal deposition along the subarachnoid portions of the seventh and eighth cranial nerves seen at autopsy. \textsuperscript{34}

It is unclear, however, what causal role calcium oxalate deposition plays. Direct mechanical injury from crystals, inflammatory response triggered by ethylene glycol metabolites, meningitis, and pyridoxine deficiency all have been proposed as mechanisms. Because the syndrome has been reported only since 1978, it is possible that the advent of hemodialysis has allowed more patients with potentially lethal ingestions of ethylene glycol to survive to display delayed neurologic complications.

### Diagnostic Strategies

Useful laboratory tests for evaluating a patient with potential ethylene glycol toxicity include serum electrolytes, calcium, BUN, creatinine, serum glucose, serum osmolality, blood ethanol level, arterial blood gases, ethylene glycol level, electrocardiogram, and urinalysis. Although crystalluria is considered the hallmark of ethylene glycol ingestion, its absence does not rule out the diagnosis because less than half of patients have this finding. \textsuperscript{30,35} Crystalluria may take the form of envelope-shaped calcium oxalate dihydrate crystals or needle-shaped calcium oxalate monohydrate crystals, which are occasionally mistaken for hippurate crystals. \textsuperscript{5} Other crystal shapes and composites have been noted so that in the setting of combined anion and osmolar gap elevation, the presence of \textit{any} type of crystalluria warrants a search for ethylene glycol. Monohydrate crystals are thought to be more specific for ethylene glycol poisoning. \textsuperscript{30} Irrigating the urinary bladder with 50 to 100 mL of saline, centring the irrigant, and examining the sediment for crystals may yield the diagnosis in patients who are already anuric. Other findings reflecting tubular dysfunction include decreased specific gravity, proteinuria, microscopic hematuria, pyuria, and cylindruria. Falsely elevated ethylene glycol levels may be seen in the face of elevated lactate or LDH with certain enzymatic assays.

Freshly voided urine can be examined for fluorescence with a Wood’s lamp. Sodium fluorescein is added to antifreeze to aid in the detection of radiator leaks. Urinary fluorescence may be seen 6 hours after ingestion of fluorescein-containing antifreeze. Gastric contents and the patient’s skin or clothing also may fluoresce under a Wood’s lamp. The lack of fluorescence does not rule out ethylene glycol ingestion, however, because examiner sensitivity, specificity, and inter-rater reliability are low. \textsuperscript{36} One study found urinary fluorescence in all specimens from children evaluated for conditions unrelated to poisoning. \textsuperscript{37} Specimens should be collected in borosilicate glass test tubes or deposited directly onto gauze or filter paper because many plastic specimen containers and some glass tubes are fluorescent. The urine pH also should be checked and adjusted to 4.5 or greater before Wood’s lamp examination.

Leukocytosis may be seen in ethylene glycol poisoning, with a typical white blood cell count of 10,000 to 40,000/μL, but is neither a sensitive nor a specific finding and is not of diagnostic value. The hematocrit and platelet counts are normal. One third of patients have hypocalcemia, which is most likely caused by calcium precipitation with oxalate. \textsuperscript{34} QT prolongation on the electrocardiogram leads to the early diagnosis of hypocalcemia. Rarely, profound hypocalcemia resulting in seizures and tetany may occur. The CK can be elevated owing to toxic effects of ethylene glycol metabolites on muscle tissue. \textsuperscript{38}

Similar to methanol, ethylene glycol often causes a profound anion gap metabolic acidosis when the metabolites glycolic acid and glyoxylic acid (and, to some extent, lactic acid) accumulate. Artificial elevations of lactic acid levels may occur in the presence of glycolate with certain analyzers. \textsuperscript{39} Similar to methanol toxicity, an elevated osmolar gap as measured by freezing point depression is a clue to the diagnosis of ethylene glycol toxicity. Lethal concentrations can be associated, however, with a normal or only slightly elevated osmolar gap. The cerebrospinal fluid may be normal or may display a cloudy or bloody appearance, increased protein or, most commonly, a polymorphonuclear pleocytosis.

Imaging studies show cerebral edema with decreased attenuation in the mediobasilar portions of the brain, typically with a return to isodensity within 1 week; this does not correspond to the clinical picture. \textsuperscript{8} MRI in one patient with delayed cranial neuropathy showed gadolinium enhancement of cranial nerve V bilaterally, possibly secondary to calcium oxalate deposition. Electroencephalographic findings have been nonspecific.

### Differential Considerations

Classically, patients who ingest ethylene glycol appear intoxicated without the odor of ethanol and have an anion gap metabolic acidosis, increased osmolar gap, and calcium oxalate crystalluria. Without evidence of alcoholic ketoacidosis or diabetic ketoacidosis, the differential diagnosis of the “double gap” should include methanol and ethylene glycol. The hallmark finding with late presentation is renal toxicity. Toxictant-induced acute renal failure is extensively reviewed elsewhere; substances commonly implicated include antimicrobials, nonsteroidal anti-inflammatory drugs, acetaminophen, halogenated hydrocarbons, radiocontrast media, metals, antineoplastic agents, and myoglobin. Hypocalcemia and a prolonged QT interval are important diagnostic clues. Toxictant-induced hypocalcemia is unusual and may be related to aminoglycosides, calcitonin, cisplatin, loop diuretics, interferon-alfa, mithramycin, pentamidine, and phosphate infusions. Healthy individuals with dietary excesses of vitamin C or foods rich in oxalate, such as tomatoes, garlic, spinach, rhubarb, cocoa, and tea, may exhibit calcium oxalate crystalluria.

### Management

Methanol and ethylene glycol ingestions are treated essentially the same, and the following recommendations apply to both. As in any overdose setting, resuscitation and stabilization are paramount. Specific blood levels that confirm the presence of these substances may not be readily available, and a delay in instituting therapy can lead to irreversible organ damage or death. For any significant history of exposure, treatment should be initiated pending a confirmatory toxic alcohol blood level.

Because methanol and ethylene glycol are absorbed rapidly from the gastrointestinal tract, and gastric emptying has not been shown to alter clinical course or outcome and may be associated with complications, its use is restricted to patients who have ingested a substantial volume and arrive in the emergency department within 30 to 60 minutes of ingestion. Even in these cases, it is of dubious value. Activated charcoal is not useful. Obtunded patients should receive intravenous (IV) naloxone, dextrose (or have a bedside glucose determination), and thiamine, if clinically indicated. Forced diuresis is of no value and may cause pulmonary edema and ARDS. Early intubation may be indicated to protect the airway against
